Removal of In-Dwelling Catheter. When removing an in-dwelling catheter, you promote normal bladder function and prevent trauma to the urethra.

To remove a catheter, you need a clean, disposable towel; a discard receptacle; a sterile syringe that is the same size as the volume of solution within the catheter's inflated balloon; and disposable gloves. The end of the catheter contains a label that denotes the volume of solution (5 to 30 mL) within the balloon.

Assist the patient into the same position as during catheterization. Some institutions recommend collecting a sterile urine specimen at this time or sending the catheter tip for culture

► SKILL 43-4 Closed and Open Catheter Irrigation

Delegation Considerations

Although closed catheter irrigation poses less risk of infection, neither closed nor open catheter irrigation is usually delegated to unregulated care providers (UCPs). Catheter irrigation is usually done in patients with complications such as UTIs or after a prostatectomy.

- UCPs may assist with other aspects of patient care, such as positioning the patient and measuring intake and output.
- Instruct the UCP to report any complaints of pain, discomfort, or fever to a nurse.
- Instruct the UCP to report the presence of clots in the output or a change in output to a nurse.

Equipment

- When using the closed intermittent method:
 - Sterile irrigation solution at room temperature
 - Sterile graduated container
 - Sterile 30 to 50 mL syringe
 - Sterile 19- to 22-gauge 2.5 cm needle
 - Antiseptic swab
 - Clamp for catheter or tubing
 - Bath blanket
- When using the closed continuous method:
 - Sterile irrigation solution at room temperature
 - Irrigation tubing and clamp (with or without Y connector)
 - IV pole
 - Y connector (optional)
 - Antiseptic swab
 - Bath blanket
- When using the open method:
 - Sterile irrigation set with tray
 - Bulb syringe or 60 mL piston-type syringe
 - Sterile collection basin
 - Waterproof drape
 - Sterile solution container
 - Antiseptic swabs
 - Sterile gloves
 - Sterile correct irrigation solution at room temperature
 - Tape or elastic band to resecure catheter
 - Bath blanket

Procedure

STEPS

1. Assess physician's order for type of irrigation and irrigation solution to use.
2. Assess colour of urine and presence of mucus or sediment.
3. Determine type of catheter in place:
 - A. Triple lumen (one lumen to inflate balloon, one to instill irrigation solution, one to allow outflow of urine).
 - B. Double lumen (one lumen to inflate balloon, one to allow outflow of urine).
4. Determine patency of drainage tubing.
5. Assess amount of urine in drainage bag (may want to empty drainage bag before irrigation).
6. Explain procedure and purpose to patient.
7. Perform hand hygiene and apply disposable gloves for closed methods.
8. Provide privacy by pulling bed curtains closed. Fold back covers so that the catheter is exposed. Cover patient's upper torso with bath blanket.
9. Assess lower abdomen for bladder distension.
10. Position patient in dorsal recumbent or supine position.
11. *Closed intermittent irrigation (with double-lumen catheter):*
 - A. Prepare prescribed sterile solution in sterile graduated cup.
 - B. Draw sterile solution into syringe by using aseptic technique.

RATIONALE

- Ensures proper selection of equipment.
- Determines whether patient is bleeding, has infection, or is sloughing tissue.
- Triple lumen is for closed continuous irrigation.
- Double lumen is for closed intermittent or open irrigation.
- Ensures that drainage tubing is not kinked, clamped incorrectly, or looped.
- If drainage bag is not empty, you will need to subtract urine volume from the amount drained to determine whether all irrigant has returned.
- Helps patient relax and cooperate during procedure.
- Prevents transmission of microorganisms.
- Promotes patient comfort
- Detects whether catheter is malfunctioning or blocking urinary drainage.
- Promotes patient comfort and provides easy access to catheter.
- Ensures that irrigating fluid remains sterile.

Critical Decision Point: Avoid cold solution as irrigant because it may cause bladder spasm and discomfort.

- C. Clamp in-dwelling catheter just distal to soft injection (specimen) port.

- Occlusion of catheter provides resistance against which irrigant can be forcefully instilled into catheter.

Continued

► SKILL 43-4 Closed and Open Catheter Irrigation—cont'd

- D. Cleanse injection port with antiseptic swab (same port used for specimen collection).
 - Reduces transmission of infection.
- E. Insert needle of syringe through port at 30-degree angle toward bladder.
 - Ensures that needle tip enters lumen of catheter and flow is directed into bladder.
- F. Slowly inject fluid into catheter and bladder.
 - Slow, continuous pressure dislodges clots and sediment without traumatizing the bladder wall.

Critical Decision Point: If catheter does not irrigate easily, the tip may be incorrectly placed in the urethra and not in the bladder. Use slow pressure when injecting fluid. Too much pressure may traumatize the urethral or bladder wall.

- G. Withdraw syringe, remove clamp, and allow solution to drain into drainage bag. If ordered by physician, keep clamped to allow solution to remain in bladder for a short time (20 to 30 minutes).
 - Allows drainage by gravity.

Critical Decision Point: If solution is to remain in bladder, do not forget to unclamp tubing at the end of the instillation period.

12. Closed continuous irrigation (with triple-lumen catheter) (see Step 12 illustration).

Step 12 Closed continuous bladder irrigation.

- A. Using the aseptic technique, insert tip of sterile irrigation tubing into bag of sterile irrigating solution.
 - Prevents entrance of microorganisms.
- B. Close clamp on tubing and hang bag of solution on IV pole.
 - Removes air from tubing.
- C. Open clamp and allow solution to flow through tubing, keeping end of tubing sterile. Close clamp.
 - Third lumen or Y connector provides means for irrigation solution to enter bladder. System must remain sterile.
- D. Wipe off irrigation port of triple-lumen catheter, or attach sterile Y connector to double-lumen catheter and then attach to irrigation tubing.
 - Ensures that urine and irrigation solution will drain from bladder.
- E. Be sure that drainage bag and tubing are securely connected to the drainage port of triple-lumen catheter or other arm of Y connector.

► SKILL 43-4 Closed and Open Catheter Irrigation—cont'd

- F. For intermittent flow, clamp tubing on drainage system, open clamp on irrigation tubing, and allow prescribed amount of fluid to enter bladder (100 mL is normal for adults). Close irrigation clamp and then open drainage tubing clamp. (Optional: Leave clamp closed for 20 to 30 minutes if ordered. See previous critical decision point.)
 - G. For continuous drainage, calculate drip rate and adjust clamp on irrigation tubing accordingly. Be sure that clamp on drainage tubing is open and check volume of drainage in drainage bag. Ensure that drainage tubing is patent, and avoid kinks.
13. Open irrigation (with double-lumen catheter):
- A. Open sterile irrigation tray, establish sterile field, pour required volume of sterile solution into sterile container, and replace cap on large container of solution.
 - B. Apply sterile gloves.
 - C. Position sterile waterproof drape under catheter.
 - D. Aspirate 30 mL of solution into sterile irrigating syringe.
 - E. Move sterile collection close to patient's thighs.
- F. Disconnect catheter from drainage tubing, allowing urine from catheter to flow into collection basin. Allow urine in tubing to flow into drainage bag. Cover end of tubing with sterile protective cap. Position tubing in a safe place.
 - G. Insert tip of syringe into catheter lumen, and gently instill solution.
- Fluid instills through catheter into bladder, flushing system. Fluid drains out after irrigation is completed.
 - Ensures continuous, even irrigation of catheter system.
 - Prevents accumulation of solution in bladder, which may cause bladder distension and possible injury.
 - Adheres to principles of surgical asepsis (see Chapter 32).
 - Reduces transmission of infection.
 - Prevents soiling of bed linens.
 - Prepares irrigant for instillation into catheter.
 - Prevents soiling of bed linens and prohibits reaching over sterile field.
 - Maintains sterility of inner aspect of catheter and drainage tubing and reduces potential of introducing pathogens into bladder.
 - Gentle instillation reduces incidence of bladder spasm but clears catheter of obstruction.

Critical Decision Point: If resistance is noted, do not force the irrigation.

- H. Withdraw syringe, lower catheter, and allow solution to drain into basin. Repeat instillation until prescribed solution has been used or until drainage is clear (will depend on purpose of irrigation).
 - I. If solution does not return, have patient turn onto his or her side facing you. If changing position does not help, reinsert syringe and gently aspirate solution.
 - J. After irrigation is complete, remove protector cap from tubing, cleanse end with alcohol swab (or recommended agency solution), and re-establish drainage system.
14. Reanchor catheter to patient with tape or elastic tube holder.
15. Assist patient to comfortable position.
16. Lower bed to lowest position. Raise side rails if appropriate.
17. Dispose of contaminated supplies, remove gloves, and perform hand hygiene.
18. Calculate fluid used to irrigate bladder and catheter and subtract from total output.
19. Assess characteristics of output: viscosity, colour, and presence of matter (e.g., sediment, clots, blood).
- Allows drainage to flow by gravity. Provides for adequate flushing of catheter.
 - Change of position may move catheter tip in bladder, increasing likelihood that instilled fluid will flow out.
 - Reduces entrance of microorganisms into system.
 - Prevents trauma to urethral tissue.
 - Promotes relaxation and rest.
 - Promotes patient safety.
 - Prevents spread of infection.
 - Determines accurate urinary output.
 - Evaluates results of irrigation.

Unexpected Outcomes

Irrigating solution does not return or is not flowing at prescribed rate, possible occlusion of catheter

Cloudy or foul urine, fever

Increase in bladder spasms, possible occlusion of catheter with foreign object (e.g., blood clot)

Related Interventions

- Examine tubing for kinks, clots, or urine sediment.
- Notify physician if irrigant is retained, if patient complains of pain, or if bladder is distended.
- Monitor fever.
- Notify physician.
- Obtain sterile urine specimen if ordered by physician.
- Notify physician.
- May be instructed to perform intermittent irrigations until clots clear.

Continued

► SKILL 43-4 Closed and Open Catheter Irrigation—cont'd

Recording and Reporting

- Record type and amount of irrigation solution used, amount returned as drainage, and the character of drainage.
- Record and report any findings such as complaints of bladder spasms, inability to instill fluid into bladder, or presence of blood clots.

Home Care Considerations

- If patient is discharged with an in-dwelling catheter and requires bladder irrigations, either the patient or the patient's family must be properly instructed on how to perform this task.
- In the home, it is most likely that open irrigation will be required. Because this method poses the highest risk of contamination, you must assess the level of understanding of surgical asepsis by the patient and his or her family.

and sensitivity tests. After removing the tape that holds the catheter in place, put a towel between a female patient's thighs or over a male patient's thighs. Insert the syringe into the injection port. Most ports are self-sealing and require that only the tip of the syringe be inserted. Slowly withdraw all of the solution to deflate the catheter's balloon fully. If any solution remains, the partially inflated balloon will traumatize the urethral canal as the catheter is removed. After deflation, explain that the patient may feel a burning sensation as the catheter is withdrawn. Pull the catheter out smoothly and slowly.

It is normal for the patient to experience some dysuria, especially if the catheter was in place for several days or weeks. Until the bladder regains full tone, the patient also may experience urinary frequency or retention.

Assess the patient's urinary function by noting the first voiding after catheter removal and by documenting the time and amount of voiding during the next 24 hours. If amounts are small, frequent assessment of bladder distension is necessary. If eight hours elapse without voiding or if the patient experiences discomfort, it may become necessary to reinsert the catheter.

Alternatives to Urethral Catheterization. Two alternatives for urinary drainage can be used to avoid the risks associated with catheters inserted through the urethra: suprapubic catheterization and condom catheters.

Suprapubic Catheterization. Suprapubic catheterization involves surgical placement of a catheter through the abdominal wall above the symphysis pubis and into the urinary bladder. A physician performs the procedure under local or general anaesthesia. The catheter is anchored in place with sutures, a commercially prepared body seal, or both. Urine drains into a urinary drainage bag. Maintenance of the tubing and drainage bag is the same as for an in-dwelling catheter. The suprapubic catheter is relatively painless and reduces the incidence of infection commonly seen with in-dwelling catheters. Studies comparing the use of this method of urinary drainage have shown mixed results. While infection rates may be slightly lower, the long-term complications are similar (Doughty, 2006). Sediment, clots, encrustations, or the abdominal wall itself can block the suprapubic catheter. Adequate fluid intake will help minimize the risk of blockage by sediment or infection due to stagnation. The suprapubic catheter must remain patent at all times. You must monitor the patient's intake and output carefully, monitor the appearance of urine, and observe for signs of infection (e.g., fever and chills). You also should administer skin care around the insertion site.

Condom Catheters. The second alternative to catheterization is the condom catheter (external urinary catheter; Box

43-11), which may be suitable for incontinent or comatose men who still have complete and spontaneous bladder emptying. The condom is a soft, pliable, rubber sheath that slips over the penis. It may be worn at night only or continuously, depending on the patient's needs. One method used to secure the condom catheter involves a strip of elastic tape or rubber that encircles the top of the condom to hold it in place. An alternative is to use a self-adhesive condom sheath. Care must be taken to ensure that whatever type or size of condom is used, blood supply to the penis is not impaired. Standard adhesive tape should never be used to secure a condom catheter because this tape does not expand with changes in penis size and is painful to remove.

The end of the condom is attached to plastic drainage tubing that can be attached to the side of the bed or strapped to the patient's leg. The condom catheter itself poses little risk of infection. Infections usually result from buildup of secretions around the urethra, trauma to the urethral meatus, or buildup of pressure in the outflow tubing. Condom catheters must be applied and changed according to the manufacturers' directions to prevent abrasion, dermatitis, ischemia, necrosis, edema, and maceration of the penis. Frequent skin assessment is vital.

If the condom catheter is made of opaque material, you should remove it daily to check for skin irritation. Some new condom catheters are transparent, and the skin may be observed through them more easily. During each catheter change, thoroughly clean the urethral meatus and penis. The drainage tubing must be checked often for patency.

For a man with a retracted penis, maintaining a conventional condom catheter may prove difficult. Special devices are available to help alleviate this problem (Figure 43-17). Manufacturer's guidelines for product application should be consulted.

No collection devices for women are as effective as the condom catheter is for men; usually the only incontinence devices used are pads and protective clothing. To maintain the patient's dignity, pads and protective clothing should not be referred to as adult diapers, and they should be changed frequently to control odour. These devices should be used only temporarily to minimize or prevent episodes of incontinence while treatment is ongoing. Patients should be monitored frequently and good skin care should be provided to prevent irritation caused by urine.

Maintenance of Skin Integrity. Urine is irritating to skin and when in continuous contact with the skin becomes alkaline, causing dermatitis and skin breakdown. Continuous exposure of the perineal area or skin around an ostomy leads to gradual maceration and excoriation (see Chapter 46).

► BOX 43-11 Procedural Guideline

Condom Catheter

Delegation Considerations:

The application of a condom catheter can be delegated to unregulated care providers (UCPs). The registered nurse is responsible for assessing the condition of the penis over time and should inform the UCP to notify the registered nurse of any signs of skin irritation or tissue swelling.

Equipment:

- Condom catheter (may be self-adhesive or provided with elastic adhesive)
- Collection bag
- Basin with warm water
- Towel and washcloth
- Disposable gloves
- Scissors

Procedure:

1. Check physician's order.
2. Perform hand hygiene.
3. Assess urinary elimination patterns, the patient's ability to urinate voluntarily, and continence.
4. Assess the patient's mental status to determine appropriate teaching related to condom catheter care.
5. Assess condition of penis and scrotum. Ensure that the foreskin of the uncircumcised male is not retracted.
6. Assess the patient's knowledge of the purpose of the condom catheter.
7. Explain procedure to patient.
8. Raise bed to working height and raise far upper side rail.

Step 13 Distance between end of penis and tip of catheter.

9. Using sheet, drape patient so that only genitals are exposed.
10. Prepare condom catheter and drainage system (see manufacturer's directions).
11. Apply gloves and provide perineal care.
 - A. If necessary, clip hair at base of penile shaft.
12. Apply skin preparation to penile shaft and allow to dry.
13. Holding penis in nondominant hand, apply condom by rolling smoothly onto penis. *Note:* Leave a 2.5 cm to 5 cm space between tip of penis and end of catheter (see Step 13 illustration)
14. Secure condom catheter:
 - A. If elastic adhesive is used, wrap the strip of adhesive over the condom catheter to secure it in place, using a spiral technique (see Step 14A illustration). *Note:* Adhesive tape must never be used.
 - B. If self-adhesive catheter is used, follow the manufacturer's directions.
15. Attach catheter to drainage bag and attach drainage bag to lower bed frame.
16. Make patient comfortable.
17. Observe urinary drainage, drainage tube patency, condition of penis, and tape placement.

Step 14A Elastic tape is applied in spiral fashion to secure the condom catheter to the penis.

Washing with pH-balanced soap and warm water is the best way to remove urine. Body lotion keeps skin moisturized, and petroleum-based ointments provide a barrier to urine. Patients who soil their clothing should receive partial baths and dry clothing and bed linens immediately after voiding. If the skin becomes irritated or inflamed, the physician may prescribe a cream or spray containing steroids to reduce inflammation. If fungal growth develops, the antifungal drug nystatin, available in cream or powder, is effective.

Promotion of Comfort. Patients with urinary alterations become uncomfortable as a result of the symptoms of urinary problems. Frequent or unpredictable voiding, dysuria, and painful distension are all sources of discomfort.

If the patient has local discomfort, a warm sitz bath may soothe inflamed tissues near the urethral meatus by improving blood supply. The patient is often relaxed after a sitz bath, and voiding occurs easily. Pain due to distension cannot be relieved unless the patient is able to empty the bladder. Interventions

Figure 43-17 Retracted penis pouch external urinary device.

that stimulate micturition or intermittent catheterization may be the only sources of pain relief.

Conservative Therapies to Restore Bladder Control and Promote Continence

The following therapies can help incontinent patients of all ages to maintain and regain control over urination:

- Pelvic floor muscle exercises to strengthen the pelvic floor
- Initiating a voiding schedule
- Using methods to initiate voiding (e.g., running water and stroking the inner thigh)
- Using relaxation techniques to aid complete bladder emptying (e.g., reading and deep breathing)
- Never ignoring the urge to void (if urinary problem involves infrequent voidings that result in retention)
- Minimizing ingestion of tea, coffee, other caffeinated drinks, and alcohol
- Taking prescribed diuretic medication or fluids that increase diuresis (such as tea or coffee) early in the morning
- Progressively lengthening or shortening periods between voiding as appropriate for control of specific cause of incontinence
- Offering protective undergarments to contain urine and to reduce the patient's embarrassment (not diapers)
- Following a weight-control program if obesity is a problem

Numerous therapies can help restore normal urinary voiding function, including surgical, pharmacological, and behavioural options. Conservative therapies should be the first line of treatment because they generally are noninvasive, have few side effects, and are feasible for older as well as younger adults (Box 43-12). Conservative therapies include lifestyle modification, pelvic floor muscle exercises, bladder training, habit retraining, and prompted voiding (RNAO, 2005). Because the success of all these therapies necessitates changes in daily lifestyle and ongoing adherence, it is important that you provide support and follow-up to enhance motivation. If conservative therapies do not eliminate the urinary alteration, then self-catheterization may restore a measure of control to the patient.

Lifestyle Modification. Several lifestyle factors have been associated with urinary incontinence. Smoking has been associated with increased risk of incontinence, likely due to the chronic cough experienced by smokers (Chung & Pavord,

* BOX 43-12 RESEARCH HIGHLIGHT

Promoting Conservative Therapies for Older Adults

Research Focus

The incidence of urinary incontinence rises with age, affecting 30% to 40% of middle-aged women and 30% to 50% of older women. The least invasive treatments are recommended as the first line of therapy, yet little is known about how older women tolerate therapies such as pelvic floor muscle exercises and bladder training. It is possible that ageist attitudes, including a belief that incontinence is a normal part of aging and that older adults are not able to learn and apply new therapies at home, continue to affect the ability of older adults to obtain appropriate care.

Research Abstract

The purpose of Perrin et al.'s (2006) study was to determine the feasibility of conservative therapies, including pelvic floor muscle exercises with biofeedback and bladder training, to treat urinary incontinence in older women. A group of 10 women (cognitively intact and older than 75 years) who were attending a urology clinic or were on the waiting list for incontinence surgery participated. Before the intervention, the women learned how to complete a 72-hour bladder diary and a 24-hour pad test. They then met with a physiotherapist at the clinic six times, over a period of six to nine weeks. All received a combined approach of bladder training and pelvic floor muscle exercises with biofeedback included as a learning tool. The women were asked to carry out the exercise program three times each day at home and to record their progress.

Three women did not complete the study, one because of the demands of the study and two because of comorbidities. All seven women who completed the program said that they were comfortable with the intervention. Although some thought the exercises were difficult at first, they improved their techniques with practice. Most were also comfortable with the manual vaginal examination and the use of the vaginal probe. Some noted difficulty with completing the bladder diary, but a 95% compliance rate was reported. Three of the seven women completed the home therapy program three times a day as advised; the other four were compliant 67.5% of the time. Episodes of leakage decreased by 39%, a decrease that correlated with an improvement in reported quality of life. All of the women reported that they would recommend the treatment to a friend. The researchers concluded that physical therapies and even biofeedback with vaginal probes are feasible in women older than 75 years.

Evidence-Informed Practice

- Incontinence, frequency, or both, are experienced by adults of all ages, educational levels, economic status, and health status.
- Many adults wrongly believe that urinary incontinence and frequency are an expected part of the aging process.
- The use of biofeedback and conservative therapies is generally well tolerated by older adults.
- Nurses can support the use of conservative, inexpensive nonpharmacological interventions to enhance comfort in community-based and some institutionalized older adults.

Reference: Perrin, L., Dauphinee, S., Corcos, J., Hanley, J., & Kuchel, G. (2006). Pelvic floor muscle training with biofeedback and bladder training in elderly women. *Journal of Wound, Ostomy, and Continence Nursing*, 32(3), 186–199.

2008). Extra weight, particularly in obese and moderately obese individuals, is believed to increase intrapelvic pressure; in one study, women who lost an average of 15 kg experienced a 51% reduction in incontinent episodes (Hunnskaar, 2008).

Caffeine contributes to urinary incontinence as it has a diuretic action and irritant effect (Cassel & Skelly, 2006). You can play an important role in educating, counselling, and supporting the patient to enable lifestyle modification that reduces the risk factors for incontinence.

Pelvic Floor Muscle Exercises. The pelvic floor musculature (PFM) spans the opening in the bony pelvis and combines with connective tissue to provide structural support for the pelvic organs. A well-toned PFM maintains the bladder neck in position to ensure that any increase in intra-abdominal pressure, as occurs with coughing, is transmitted not only to the bladder but also to the bladder neck to maintain closure. Contraction of the PFM results in urethral compression as the urethra is pulled forward toward the symphysis pubis (Ashton-Miller & Delancey, 2007). Weakened PFMs can result from muscle wasting caused by prolonged immobility, frequent straining in association with urinary or fecal elimination, stretching of muscles during childbirth, menopausal muscle atrophy, or traumatic damage.

Pelvic floor muscle exercises (PFMEs), also known as **Kegel exercises**, improve the strength of PFMs through hypertrophy and recruitment of additional muscle fibres associated with repetitive contractions (Ashton-Miller & DeLancey, 2007). These exercises have demonstrated effectiveness in treating stress incontinence, overactive bladders, and mixed causes of urinary incontinence (Dolman, 2007). Patients begin these exercises during voiding to learn the technique: if they are able to slow the urinary stream, they are contracting the proper muscles. The exercises are then practised at nonvoiding times (Box 43-13). Patients should be alert and motivated to perform the exercises. They also should be aware that it may take 12 to 16 weeks to notice appreciable change, but that maintaining the exercises is important to obtain a positive outcome.

Bladder Training. The goal of bladder training is to increase gradually the interval between voids and to decrease voiding frequency (Eustice, 2007). The overall purpose is to restore a normal pattern of voiding. For bladder training to be successful, patients must be alert, motivated, and physically able to follow a training program. The program includes education, scheduled voiding, and positive reinforcement.

The first step in bladder training is establishing a baseline. The patient or caregiver completes a urinary diary to assess maximum voiding intervals. It is not uncommon for the patient with frequency or an overactive bladder to void small amounts hourly or more often. An initial training schedule for such a patient might involve a voiding schedule of every 75 minutes while awake, increasing every one to three weeks by 15-minute increments toward a three-hour schedule. The rate of incremental changes will depend on the patient's progress and on his or her ability to adhere to a rigid schedule. Urge-suppression techniques, such as counting backward from 100 when the urge to void is felt and performing pelvic floor muscle contractions, are helpful. You must be aware that the patient who has experienced an episode of incontinence in public will be particularly hesitant to deter voiding for even brief periods.

Habit Retraining and Prompted Voiding. Habit retraining and prompted voiding are useful strategies for patients with cognitive or physical impairment, or both, who rely on caregiver assistance. Habit retraining involves

BOX 43-13 PATIENT TEACHING

Pelvic Floor Muscle Exercises (Kegels)

Objectives

The patient who is cognitively alert and motivated will achieve continence or experience fewer episodes of incontinence as a result of increased pelvic floor muscle tone and strength.

Teaching Strategies

- Explain the method used to identify proper muscle contraction: female patient sits on the toilet with knees apart and tightens muscles to stop the flow of urine; a male patient tries to stop the flow of urine midstream.
- After muscle is identified, instruct the patient to lie down with knees bent and apart, or to sit.
- Instruct the patient to contract the pelvic floor muscle gradually and hold the contraction for 3 to 10 seconds without tensing the muscles of the legs, buttocks, back, or abdomen. Remind the patient to breathe during the exercise.
- Instruct the patient to relax the muscle gradually for an equal time period between each contraction.
- The patient should repeat this exercise at least two or three times, and work up to 10 repetitions as it becomes easier. The patient should do this exercise two or three times a day, or as often as possible.
- Explain that within the first week of exercises, the patient and nurse can assess whether proper muscle contraction is occurring by patient placing two fingers in the vagina (or, for men, one finger in rectum) while contracting the pelvic floor muscle. The patient should feel tightening in the vagina or anus during the contraction.
- Teach the patient and the caregiver to keep a 24- to 72-hour urinary diary to identify changes in patterns of urinary elimination.

Evaluation

- Ask the patient if he or she has identified the pelvic floor muscle by finger insertion (into the vagina or rectum).
- During vaginal or rectal (male) bimanual examination, ask the patient to perform the exercises, then assess muscle tone.
- Monitor the patient's urinary diary.
- Ask the patient and the caregiver about degree of satisfaction related to the control achieved over urinary elimination.

assessment of a patient's normal pattern of voiding to establish a toileting schedule that preempts incontinence (Ostaszkie-wicz et al., 2008). Such individualized toileting schedules have demonstrated effectiveness but are labour intensive. You should help the patient to the bathroom before episodes of incontinence occur. Fluids and medications are timed to prevent interference with the toileting schedule. When combined with positive reinforcement, this approach is also called prompted voiding (Box 43-14).

Self-Catheterization. Some patients with chronic disorders such as spinal cord injury learn to perform self-catheterization. The patient must be physically able to manipulate equipment and assume a position for successful catheterization. You must teach the patient the structure of the urinary tract, the clean versus sterile technique, the importance of adequate fluid intake, and the frequency of

* BOX 43-14

EVIDENCE-INFORMED
PRACTICE GUIDELINE**Prompted Voiding for People With Urinary Incontinence**

- Approach the patient at scheduled prompted voiding times.
- Wait five seconds for the patient to initiate a request to toilet.
- Ask the patient if he or she is wet or dry.
- Physically assess the patient to determine continence status.
- Provide positive feedback if the patient is dry.
- Prompt the patient to toilet.
- Offer assistance with toileting.
- Provide feedback.
- Inform the patient of the next scheduled prompted voiding session.
- Encourage the patient to self-initiate requests to toilet.
- Record the result of the prompted voiding session.

Source: Adapted from Wyman, J. (2008). Prompted voiding. In B. Ackley, B. Swan, G. Ludwig, & S. Tucker (Eds.), *Evidence-based nursing care guidelines: Medical-surgical interventions* (pp. 696–698). St Louis, MO: Mosby.

self-catheterization. In general, the goal is to have patients perform self-catheterization every six to eight hours, but the schedule should be individualized.

❖ **Evaluation****Patient Care**

The patient is the best source of evaluation of outcomes and responses to nursing care (Figure 43-18). However, you will also evaluate the effectiveness of nursing interventions through comparisons with baseline data. You should evaluate for changes in the patient's voiding pattern, the presence of urinary tract alteration, and the patient's physical condition. Actual outcomes are compared with expected outcomes to determine the patient's health status. Continuous evaluation allows you to determine whether new or revised therapies are required or if any new nursing diagnoses have developed.

Patient Expectations

If you have developed a trust relationship with the patient, indications of the patient's degree of satisfaction with his or her care will be evident. The patient may smile or nod in appreciation. However, you need to confirm whether the patient's expectations have been met to full satisfaction. You may need to ask specifically about the patient's degree of urinary control and comfort. If simply asked, "How are you feeling today?" the patient may reply with a noncommittal "Okay." However, you need specific information about how well an intervention has met the patient's need in order to continue or to revise the care plan. You can also assist the patient in redefining unrealistic expectations when impairment in function is not likely to be altered as completely as he or she might like.

❖ **KEY CONCEPTS**

- The act of micturition, or voiding, is influenced by voluntary control from higher brain centres and involuntary control from the spinal cord.

Knowledge

- Clinical signs of normal micturition
- Characteristics of normal urine
- Behaviours that demonstrate learning

Experience

- Previous patient responses to planned nursing interventions to promote urinary elimination

Evaluation

- Reassess the patient's urination pattern and signs and symptoms of alterations
- Inspect the character of the patient's urine
- Have the patient and family demonstrate any self-care skills
- Have the patient discuss feelings regarding any permanent changes in elimination
- Ask patient if expectations are being met

Standards

- Use expected outcomes established in patient's plan of care
- Use established expected outcomes from professional organizations to evaluate the patient's response to care

Qualities

- Be accountable and responsible for onset of any complications related to care
- Demonstrate perseverance when necessary because some interventions (e.g., pelvic floor exercises) may take weeks to months to effect any change
- Adapt and revise approaches if interventions are ineffective

Figure 43-18 Critical thinking model for urinary elimination evaluation.

- Symptoms common to urinary disturbances include urgency, frequency, dysuria, polyuria, oliguria, and difficulty in starting the urinary stream.
- When collected properly, a clean-voided urine specimen does not contain bacteria from the urethral meatus.
- Methods of promoting the micturition reflex assist patients in sensing the urge to urinate and in controlling urethral sphincter relaxation.
- An increased fluid intake results in increased diluted urine formation that reduces the risk of urinary tract infections.
- An in-dwelling urinary catheter remains in the bladder for an extended period, making the risk of infection greater than with intermittent catheterization.
- Catheter irrigation is necessary when the catheter becomes occluded with sediment or blood clots.
- A catheter drainage system should be a closed system positioned to allow free drainage of urine by gravity.
- Incontinence is classified as transient, urge, stress, mixed, functional, overflow, reflex, or total. Each type has specific nursing interventions.
- Specific guidelines for catheter selection should be followed so that the catheter does not cause harm.

✦ CRITICAL THINKING EXERCISES

- Mrs. Rodriguez is 77 years old and has had problems with urgency for the past two years. The episodes are becoming increasingly frequent. She has been attempting to deal with the problem by using an absorbent pad in her underwear, but she feels as though everyone knows about her incontinence. The embarrassment of urinary odours often keeps her at home. She has given up attending daily mass at church.
 - How can you help Mrs. Rodriguez regain control of her urinary elimination?
 - What actual nursing diagnoses apply to Mrs. Rodriguez?
 - For one of the diagnoses, provide one goal or outcome and two nursing interventions.
- Mrs. Brownell is 37 years old and has been admitted with back pain radiating downward into her groin. She has also noticed blood in her urine for a week, but she was hoping it would go away. She is scheduled to undergo an intravenous pyelogram (IVP) in four hours.
 - What is the purpose of the IVP?
 - What nursing care is needed before Mrs. Brownell goes to the radiography department?
 - Provide at least two nursing responsibilities for care of a patient who has undergone an IVP.
- Mrs. Fenton is 70 years old and has physical limitations related to rheumatoid arthritis. Her daughter, with whom she lives, has brought her to her family practitioner's office. You are the family nurse practitioner in the practice. As you assess Mrs. Fenton, you ask her how she is coping. She begins to answer but then starts to cry and says, "I know when I have to go to the bathroom, but I often don't make it in time." Her daughter asks you for suggestions on how to manage, as she has noticed that her mother's perineal skin is reddened and sore. What assessments need to be completed before planning interventions for Mrs. Fenton's care?
- Hospital-acquired UTIs are often related to poor hand hygiene and
 - Urinary drainage bags
 - Poor perineal hygiene
 - Poor catheterization technique
 - Poor urinary output
- The urine appears concentrated and cloudy because of the presence of white blood cells (WBCs) or
 - Bacteria
 - Urinary drainage bags
 - Blood clots
 - Poor perineal hygiene
- Prompted voiding is most appropriate for
 - Patients with cognitive disorders
 - Patients with small-capacity bladders
 - Patients with urinary obstruction
 - Male patients after prostatectomy
- A patient with stress incontinence
 - Is incontinent after a strong urge to void
 - Is unaware of the need to void
 - Loses small amounts of urine with increased intra-abdominal pressure (e.g., coughing)
 - Exhibits a small-capacity bladder
- Ensuring that an in-dwelling catheter drainage bag is lower than the bladder prevents
 - Urine flowing back into the bladder, which will likely cause an infection
 - Urinary retention
 - Reflex incontinence
 - Urinary incontinence

✦ REVIEW QUESTIONS

- The normal adult urine output is
 - 1000 mL/day
 - 1500 to 1600 mL/day
 - 3000 to 3200 mL/day
 - 4000 mL/day
- Renal alterations result from factors that cause injury directly to the glomeruli or renal tubule, interfering with their normal filtering, reabsorptive, and secretory functions. Selected causes include
 - Transfusion reactions
 - Dehydration
 - Hemorrhage
 - Heart failure
- Postrenal alterations result from obstruction to the flow of urine in the urinary collecting system caused by
 - Dehydration
 - Calculi
 - Hemorrhage
 - Diabetes mellitus
- Which of the following is *not* a risk factor for UTI?
 - Catheterization
 - Antibiotic use
 - Acidic urine
 - Spermicide use
- When applying a condom catheter, it is important to secure the catheter on the penile shaft in such a manner that the catheter is
 - Tight and draining well
 - Dependent and draining well
 - Secured with adhesive tape applied in a circular pattern
 - Snug and secure, but does not cause constriction to blood flow
- The nurse can provide support to the patient with incontinence by
 - Discussing long-term care placement
 - Recommending long-term catheterization
 - Referring to local continence services and Web sites
 - Informing the patient that nothing can be done
- Lifestyle choices to improve incontinence include
 - Immunization
 - Weight loss
 - Cholesterol management
 - Regular medical examination

✦ RECOMMENDED WEB SITES

Canadian Nurse Continence Advisors Association (CNCA): <http://www.cnca.ca/index.htm>

This national association is mandated to enhance the specialty of Nurse Continence Advisors (NCA) in Canada by promoting education, research, and clinical practice.

The Canadian Association for Enterostomal Therapy: <http://www.caet.ca>

The Canadian Association for Enterostomal Therapy (CAET) is a professional organization that represents enterostomal therapy nurses, who provide services for patients with abdominal stomas (openings), fistulae, draining wounds, or selected skin, gastrointestinal, and genitourinary disorders. CAET promotes education, standards, and research for enterostomal practice.

The Canadian Continence Foundation: <http://www.continence-fdn.ca>

The Canadian Continence Foundation is a national, nonprofit organization that serves the education needs of people experiencing incontinence. The foundation implements and promotes professional education and research to advance treatment and management of incontinence.

The Kidney Foundation of Canada: <http://www.kidney.ca>

This national volunteer organization is committed to reducing the burden of kidney disease through funding research, providing education and support, promoting access to health care, and increasing public awareness about kidney health and organ donation.

United Ostomy Association of Canada Inc.: <http://www.ostomycanada.ca>

United Ostomy Association of Canada Inc. is a voluntary organization dedicated to assisting people with bowel or bladder diversions by providing support and information.

Bowel Elimination

Original chapter by Lori Klingman, RN, MSN

Canadian content written by Jennifer Skelly, RN, PhD, and Melissa Northwood, RN, MSc, GNC(C)

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss the role of gastrointestinal organs in digestion and elimination.
- Describe the integrated processes of oral pharyngeal swallowing and breathing.
- Describe the functions of the large intestine.
- Explain the physiological aspects of normal defecation.
- Discuss the psychological and physiological factors that influence the elimination process.
- Describe the common physiological alterations in elimination.
- Assess a patient's pattern of elimination.
- List the nursing diagnoses related to alterations in elimination.
- Describe the nursing implications for common diagnostic examinations of the gastrointestinal tract.
- List the nursing measures that promote normal elimination.
- List the nursing measures included in bowel training.
- Discuss the nursing measures required for patients with a bowel diversion.
- Use critical thinking in the provision of care to patients with alterations in bowel elimination.

Bowel elimination is crucial to human function and hence critical for nurses to understand in the care of their patients. The gastrointestinal system is a remarkable structure that allows the ingestion of food and absorption of nutrients and, ultimately, the elimination of waste.

Regular elimination of bowel waste is essential for normal body functioning. Alterations in bowel elimination are often early indications of problems within either the gastrointestinal (GI) tract or another body system.

To manage the bowel elimination problems of patients, you must understand the normal elimination process and the factors that promote, impede, or cause alterations in elimination. Of particular concern in managing bowel elimination is supportive nursing care that is respectful of the patient's privacy and emotional needs.

Scientific Knowledge Base

The purposes of the GI tract are to ingest food, break down the ingested food into absorbable forms (digestion), absorb fluid and nutrients, prepare food for both absorption and use by the body's cells, and provide temporary storage of feces (Figure 44-1). The GI tract is a series of hollow, multilayered, muscular organs that are lined with mucous membranes. The mucosal and muscle layers are innervated by the intrinsic enteric nervous system comprising sensory, interneuronal, and motor fibres. The rate of rhythmic contractions is specific to each organ and is controlled by the pacemaker cells in the muscle layers. The central nervous system receives input from the gastrointestinal tract through sensory fibres, which travel in the vagus and sympathetic nerves. Extrinsic sympathetic and parasympathetic motor nerves terminate on the enteric nervous system and act to modulate the activity of the intrinsic enteric nervous system. The GI tract begins at the mouth and continues through to the anus. The mouth, esophagus, and stomach receive food, and initial digestion occurs. The duodenum, jejunum, and ileum are where most digestion and absorption occurs. Finally, the cecum, colon, and rectum store and then eliminate waste. The salivary glands, liver, and pancreas are accessory organs that aid digestion. The GI tract also functions as a specialized immune system, preventing bacteria and viruses of the nonsterile lumen from entering the bloodstream (Hannon & Porth, 2010).

Mouth

The mouth is the point of entry into the GI tract. The mouth mechanically and chemically breaks down nutrients into usable sizes and forms. The teeth **masticate** food, breaking it

down into a soft, moist ball (a **bolus**) suitable for swallowing. Saliva, which is produced by the salivary glands in the mouth, dilutes and softens the food in the mouth for easier swallowing and commences digestion of carbohydrates. In addition, mucus from the salivary glands lubricates the passage of the bolus through the pharynx and down the esophagus during swallowing.

Swallowing begins with the lips closing and the tongue curling with its tip and then the back being pressed to the roof of the mouth (Figure 44-2). The action of swallowing tips the bolus into the pharynx. The pharyngeal cavity is common to both the gastrointestinal tract and the respiratory tract. The swallowed bolus must cross the nasopharynx, and the soft palate must elevate toward the nasopharynx to prevent material from entering the back of the nose. To prevent aspiration, the vocal cords in the glottis close, the epiglottis moves downward to seal off the trachea, and breathing is inhibited in the central nervous system. The bolus enters the esophagus through the relaxed upper esophageal sphincter. This complex process is under striated muscle control and requires an intact nervous system (Hannon & Porth, 2010).

Esophagus

The esophagus provides a conduit to the stomach through the chest cavity. The esophagus is a straight tube about 25 cm in length. Smooth muscle layers of the esophagus provide the peristaltic contractions to move food along its length. Its mucous membranes secrete mucus that aids in the lubrication of food. Sphincters on either end of the esophagus prevent air from entering the esophagus and stomach during breathing and reflux of stomach contents into the esophagus (Hannon & Porth, 2010).

The bolus travels down the relaxed esophagus mainly by gravity to the lower esophageal sphincter, which is opened by the initiation of swallowing in the pharynx and upper esophageal sphincter. A wave of **peristaltic contractions** propels the bolus into the stomach. Peristaltic contractions relax over the bolus and contract behind the bolus, thus moving contents through the length of the GI tract. If the bolus moves slowly or is stuck, a local reflex will relax the area ahead of the bolus and produce a powerful contraction behind the bolus. In the esophagus, this action is known as secondary peristalsis. Tertiary contractions of the esophagus are frequently simultaneous and are produced by irritation of the mucosa by gastric contents. These contractions can be extremely painful and may mimic cardiac chest pain (Hannon & Porth, 2010).

Stomach

The stomach performs several tasks: storage of swallowed food and liquid, mixing of food with liquid and gastric digestive juices, and the controlled emptying of its contents through the pyloric sphincter into the small intestine. It is a baglike structure located in the upper quadrant of the abdomen.

Peristaltic and mixing contractions of the stomach are controlled by the intrinsic pacemaker activity of the smooth muscle cells. Similar to other sections of the GI tract, the stomach is innervated by the enteric nervous system and connections to the parasympathetic and sympathetic nervous systems. The emptying of the stomach is regulated by neural and hormonal mechanisms.

The stomach produces two key GI hormones: gastrin and ghrelin. Gastrin stimulates gastric acid secretion. Ghrelin is newly discovered and has growth-hormone-releasing activity

Figure 44-1 Organs of the gastrointestinal tract (with the heart as a reference point).

Figure 44-2 Oral and pharyngeal events during swallowing. **A**, The bolus (F) is propelled into the pharynx by placement of the tongue (T) on the roof of the hard palate. **B**, Further propulsion is caused by movement of the more distal regions of the tongue against the palate. Contraction of the upper constrictors of the pharynx and the soft palate separates the oropharynx from the nasopharynx. **C**, Contraction of the pharynx and relaxation of the cricopharyngeal muscle propel the bolus through the upper esophageal sphincter. Upward movement of the glottis and downward movement of the epiglottis (Ep) seal off the trachea (Tr), and the respiratory drive is inhibited in the central nervous system. **D**, The bolus is now in the esophagus (E) and is propelled into the stomach by a peristaltic contraction. **Source:** Johnson, L. R. (2001). *Gastrointestinal physiology* (6th ed., p. 28, Fig. 3-1). St Louis, MO: Mosby.

and stimulates food intake and digestion while reducing energy expenditures. Gastrin and somatostatin regulate the secretion of acid and pepsin in the stomach.

The stomach also secretes hydrochloric acid (HCl) and the intrinsic factor. HCl facilitates the digestion of protein and is antibacterial. The intrinsic factor is essential in the absorption of vitamin B₁₂. Mucus protects the stomach mucosa from acidity and enzyme activity (Hannon & Porth, 2010). The rate at which the stomach empties depends on the content of the dissolved and partially digested bolus (**chyme**). Water diffuses from both the stomach and the small intestine and is emptied rapidly. Carbohydrates are emptied only slightly more slowly, particularly if they are not strongly acidic. Proteins empty even more slowly and in smaller amounts as determined by the acidity of the chyme. Fats are emptied the slowest of all. The controlled emptying allows the pancreatic secretions and bile to neutralize the chyme and secrete enzymes for luminal digestion (Hannon & Porth, 2010).

Small Intestine

The small intestine consists of the duodenum, jejunum, and ileum. The duodenum is about 22 cm long and connects the stomach to the jejunum. The duodenum also contains the opening for the common bile duct and main pancreatic duct. The jejunum and ileum are over 7 m long and are folded closely to fit in the abdomen (Hannon & Porth, 2010).

The duodenum continues to process the chyme from the stomach. The chyme that enters the duodenum is acidic

and contains partially digested protein, carbohydrates, and unemulsified fats. The presence of these substances stimulates the release of the hormones secretin and cholecystokinin from the duodenal mucosa. Secretin stimulates the pancreas to secrete bicarbonate to neutralize the acid. Cholecystokinin stimulates the pancreas to secrete the following enzymes: (1) amylases, which convert carbohydrates to disaccharides; (2) proteases, which further hydrolyze proteins into smaller peptides; and (3) lipases, which hydrolyze triglycerides into fatty acids and monoglycerides. The presence of fats in the duodenum further stimulates cholecystokinin release, which causes the gallbladder to contract, which in turn releases bile to emulsify the fats. Any blockage of the release of these enzymes prevents the digestion of fats and proteins and results in large, fatty, and foul-smelling stools. Undigested fats and proteins reach the colon and are responsible for the changes in fecal appearance (Hannon & Porth, 2010).

The second section of the small intestine, the jejunum, is approximately 2.7 m long. Its primary function is the absorption of carbohydrates and proteins. The ileum, which is approximately 3.7 m long, specializes in the absorption of water, certain vitamins, iron, fats, and bile salts. Most nutrients and electrolytes are absorbed in the small intestine, specifically by the duodenum and the jejunum.

If the small intestine function is impaired, the digestive process is greatly altered. For example, conditions such as inflammation, surgical resection, or obstruction can disrupt contractile activity, reduce the area of absorption, or block the

Figure 44-3 Divisions of the large intestine.

passage of chyme. As a result, electrolyte and nutrient deficiencies can develop (Hannon & Porth, 2010).

Large Intestine

The lower GI tract is called the large intestine because it is larger in diameter than the small intestine; however, at 1.5 to 1.8 m in length, it is much shorter. The large intestine is the primary organ of bowel elimination and is divided into the cecum, the colon, and the rectum (Figure 44-3).

Chyme from the terminal ileum enters the cecum of the large intestine, propelled by waves of peristalsis through the ileocecal sphincter, a circular muscle layer that regulates ileal emptying and prevents regurgitation of fecal contents. After a meal, the gastroileal reflex causes the terminal ileum to contract regularly, and the sphincter opens with each contraction, thereby pushing the ileal contents into the colon.

The colon is divided into the ascending, transverse, descending, and sigmoid colons. The colon's muscular tissue allows it to accommodate and eliminate large quantities of waste and gas (**flatus**). The colon has three functions: absorption, secretion, and elimination. Each day, a large volume of water and significant amounts of sodium and chloride are absorbed by the colon (Doughty, 2006).

Two types of muscle contractions occur in the colon: slow-mixing contractions and mass **peristalsis** (or mass movement). Slow-mixing contractions move contents through the colon and expose the chyme to the mucosa, where active absorption of sodium and chloride causes water absorption

and dries the chyme to feces. Intestinal content is the main stimulus for the slow-mixing contractions. Mass peristalsis movements then push the feces toward the rectum. The ingestion of food is the main stimulus for mass peristalsis, which is known as the **gastrocolic reflex**. In adults, these mass movements occur only three or four times each day (Hannon & Porth, 2010).

When the slow-mixing contractions increase and the mass peristalsis diminishes, water continues to be absorbed and the feces dry out, resulting in constipation. Conversely, when the mixing movements are decreased and the mass peristalsis is increased, the water has less time to be absorbed, and the stool will be watery (diarrhea) (Hannon & Porth, 2010).

The secretory function of the colon aids in electrolyte balance. Bicarbonate is secreted in exchange for chloride. Approximately 4 to 9 mmol of potassium is also excreted daily. Extreme alterations in colon function (e.g., diarrhea) can cause severe electrolyte disturbances (Hannon & Porth, 2010).

The rectum is the final portion of the large intestine. Normally, the rectum is empty of waste products, or **feces**, until just before defecation. The rectum contains vertical and transverse folds of tissue that may help to temporarily hold fecal contents during **defecation**. Each fold contains an artery and vein that can become distended from pressure during straining. This distension can result in the formation of hemorrhoids (Doughty, 2006).

The volume of fluids absorbed by the GI tract is high. Oral fluid intake is approximately 1.2 L per day; an additional 7 L of fluid enters from the blood as the result of the secretion of digestive enzymes by the mucosa, liver, gallbladder, and pancreas, and by osmosis as the numbers of molecules in the lumen increase by digestion. Absorption from the small and large intestine amounts to 8.1 L per day, leaving 100 mL to be excreted in the feces. Therefore, maintaining fluid and electrolyte balance is a key function of the GI system (Hannon & Porth, 2010).

Anus and Rectum

Feces and flatus are expelled from the rectum through the anal canal and the anus. Contraction and relaxation of the internal anal sphincter is under autonomic (unconscious) control, whereas the external anal sphincter is under somatic neural (conscious) control. The anal canal is richly supplied with sensory and motor nerve fibres to help control continence. Additionally, the maintenance of the acute anorectal angle formed by the puborectalis and levator ani (pelvic floor) muscles plays a key role in continence (Doughty, 2006).

When feces enter the rectum, the internal anal sphincter relaxes and this enables the anal canal to determine if the contents are solid or liquid. This action occurs concurrently with the reflexive contraction of the external sphincter. Additionally, this contraction can be accompanied by a voluntary squeeze of the sphincter muscles. The rectum is able to hold feces until their presence stimulates stretch receptors in the mucosa, producing an urge to defecate. The patient then seeks out an appropriate place to defecate, assumes a squatting position to straighten the anorectal angle, and voluntarily relaxes the external sphincter. Bearing down tenses abdominal muscles. The pelvic floor muscles relax and the feces enter the lower rectum. Involuntary propulsive contractions continue until the rectum is emptied. When the last of the feces passes, the external anal sphincter reflexively closes (Bliss & Norton, 2010).

Nursing Knowledge Base

Process of Defecation

The physiological factors critical to bowel function and defecation include the acute anorectal angle; reflexes that cause the external anal sphincter to contract when the internal anal sphincter relaxes; pressure in the anal canal at rest facilitated by the internal anal sphincter and voluntary action of the external anal sphincter; sensory response of the rectum to filling with feces; absorption of fluid from the intestine to create formed stool consistency; complete evacuation of the rectum; and physical and cognitive abilities to get to the bathroom when needed (Bliss & Norton, 2010). Normal defecation should be painless, resulting in the passage of a soft, formed stool.

Defecation begins with contractions in the left colon, moving the stool toward the anus. When a stool reaches the rectum, the distension causes relaxation of the internal anal sphincter and signals an awareness of the need to defecate. At the time of defecation, the external sphincter relaxes and abdominal muscles contract to increase intrarectal pressure and force the stool out (Doughty, 2006). Pressure can be exerted to expel feces through a voluntary contraction of the abdominal muscles and the diaphragm while maintaining forced expiration against a closed airway. This action is termed the **Valsalva manoeuvre**. This action should be avoided by patients, particularly those with heart disease, as the increased intrathoracic pressure, immediate tachycardia, and reflex bradycardia can cause cardiac arrest (Marsh, 2003).

Position During Defecation. Instead of straining, patients should be taught about the optimal position to facilitate defecation. Squatting is the normal position during defecation. Toilets are designed to facilitate this posture, by allowing the person to lean forward, exert intra-abdominal pressure, and contract the thigh muscles. Bulging out the abdomen—rather than contracting the abdominal muscles—more effectively opens the bowels (Figure 44-4) (Doughty, 2006). For patients who are immobilized in bed, defecation is often difficult. In a supine position, it is impossible to contract the muscles used during defecation. If the patient's condition permits, raise the head of the bed; this action assists the patient to a more normal sitting position on a bedpan, enhancing the ability to defecate (Ostaszkiwicz et al., 2010).

Promotion of Normal Defecation. Several interventions can stimulate the defecation reflex, affect the character of feces, or increase peristalsis to help patients evacuate bowel contents normally and without discomfort.

Sitting Position. You might need to assist patients who have difficulty sitting because of muscular weakness and mobility problems. Regular toilets are too low for patients who are unable to lower themselves to a sitting position because of joint- or muscle-wasting diseases. Elevated toilet seats require less effort to sit or stand; however, they can create difficulties in achieving a squat position. In many provinces and territories, elevated toilet seats can be acquired through a service agency for minimal or no cost. The community nurse must assess the patient's capabilities in the home and the requirement for any additional equipment to facilitate daily living (Ostaszkiwicz et al., 2010).

Positioning on Bedpan. Patients restricted to bed must use bedpans for defecation. Women use bedpans to pass both urine and feces, whereas men use bedpans only for defecation. Sitting on a bedpan can be extremely uncomfortable. You need to help patients to position themselves comfortably. Two types

Correct position for opening your bowels

Figure 44-4 Correct position for opening your bowels during defecation. **Source:** Redrawn by permission of Ray Addison, Nurse Consultant in Bladder and Bowel Dysfunction, and Wendy Ness, Colorectal Nurse Specialist. Produced by Norgine Pharmaceuticals Limited, 2003.

of bedpans are available (Figure 44-5). The regular bedpan, made of metal or hard plastic, has a curved, smooth upper end, a sharp-edged lower end, and is approximately 5 cm deep. A fracture pan, designed for patients with body or leg casts, has a shallow upper end and is approximately 1.3 cm deep. The upper end of the pan fits under the buttocks toward the sacrum, and the lower end fits just under the upper thighs. The pan should be high enough so that feces enter the pan. A metal bedpan should be warmed with water first, then dried.

Ensure that you maintain the patient's privacy during bowel elimination. The call light and a supply of toilet paper should be within easy reach. When the patient finishes, respond to the call signal immediately and remove the pan. The patient likely will require assistance with wiping. To remove the pan, ask the patient to roll off to the side or to raise the hips. Hold the pan steady to avoid spilling. Avoid pulling or shoving the pan from under the patient's hips; these actions can pull the patient's skin and cause tissue injury, such as shearing (see Chapter 46). After the pan is removed, while wearing gloves, clean the anal and perineal areas.

After assessing the stool, you should immediately empty the bedpan's contents into the toilet or in a special receptacle in the utility room. The bedpan should be rinsed thoroughly. Care must be taken to avoid splashing the contents or the rinse. Avoiding spillage is of critical importance when using

Figure 44-5 Types of bedpans. From left, regular bedpan and fracture bedpan.

Figure 44-6 Positions on a bedpan. **Top**, Improper positioning of a patient. **Bottom**, Proper positioning of the patient reduces back strain.

universal infection control precautions. The patient uses the same bedpan each time. Chart the characteristics of the feces.

When positioning a patient on a bedpan, use the proper method to prevent muscle strain and discomfort. Never try to lift a patient onto a bedpan. A patient should never be placed on a bedpan and then left with the bed flat unless demanded by activity restrictions. When the bed is flat, the hips remain hyperextended.

Figure 44-6 shows proper and improper positions on a bedpan. The best method is to ensure the patient is positioned high in bed. Raise the patient's head about 30 degrees to prevent hyperextension of the back and to provide support to the upper torso. The patient then raises the hips by bending the knees and lifting the hips upward. Place your hand, palm up, under the patient's sacrum; rest your elbow on the mattress and use it as a lever to help in lifting, while slipping the pan under the patient. Patients who have had abdominal surgery are hesitant to exert strain on suture lines and may have difficulty positioning themselves on a bedpan. To prevent abrasions, do not force the pan along the patient's skin. Always wear gloves when handling a bedpan.

If the patient is immobile or if it is unsafe to allow the patient to exert such effort, you can assist the patient to roll onto the bedpan by using the following steps:

1. Lower the head of the bed flat and assist the patient to roll onto one side, backside toward you.
2. Place the bedpan firmly against the buttocks, down into the mattress with the open rim toward the patient's feet (Figure 44-7).

Figure 44-7 Positioning an immobilized patient on a bedpan.

3. Keeping one hand against the bedpan, place your other hand around the patient's far hip. Ask the patient to roll back onto the pan, flat in bed. Do not shove the pan under the patient.
4. When the patient is positioned comfortably, raise the head of the bed 30 degrees.
5. Place a rolled towel or small pillow under the lumbar curve of the patient's back for added comfort.
6. Raise the knee gatch or ask the patient to bend the knees to assume a squatting position. Do not raise the knee gatch if contraindicated (Doughty, 2006).

Factors Affecting Normal Bowel Elimination

Many factors influence the process of bowel elimination. Knowledge of these factors enables you to anticipate measures required to maintain a normal pattern of bowel elimination.

Diet. The food a person eats influences bowel elimination. Regular daily food intake helps to maintain a routine pattern of peristalsis in the colon. **Fibre**, the indigestible residue in the diet, provides the bulk of fecal material. Dietary fibre is classified as insoluble and soluble fibre. Insoluble fibre is found in whole grains, wheat bran, and vegetables and does not dissolve in water. It is effective in preventing constipation. Soluble fibres are found in some beans, certain fruits and vegetables, and wheat bran. Soluble fibre forms a gel when mixed with water and is not as effective in preventing constipation. When a patient's dietary fibre is low, the stool becomes dry, hard, and difficult to pass (Registered Nurses' Association of Ontario [RNAO], 2011).

Ingestion of a high-fibre diet or taking a fibre supplement can improve the likelihood of a regular bowel elimination pattern if other factors are normal. However, because fibre retains fluid in the GI tract, when additional fibre is ingested, adequate fluid intake is essential; inadequate fluid intake can lead to serious constipation or impaction. Recommended daily fluid intake for adults is at minimum 1.5 litres.

Intolerances to certain foods can cause problems with bowel elimination. For example, **lactose intolerance** is the inability to digest lactose, the predominant sugar in milk. When lactose cannot be absorbed, it acts as an osmotic laxative, resulting in diarrhea, gaseous distension, and cramping (Lomer et al., 2008). Individuals who have lactose intolerance must learn how much lactose their body can tolerate. For example, some individuals can drink one glass of milk without effect, but not two.

Fluid Intake. An inadequate fluid intake or disturbances that result in fluid loss (such as vomiting) can affect the character of feces. Fluid liquefies intestinal contents to ease their passage through the colon. Reduced fluid intake slows the passage of food through the intestine and can result in hardening of the stool. Unless a medical contraindication exists, an adult should drink six to eight glasses (1400 to 2000 mL) of noncaffeinated fluid daily (RNAO, 2011). Equally important is to avoid consuming large amounts of caffeinated beverages, such as tea and coffee, as they can be irritating to the bowel and dehydrating. Some patients find that artificial sweeteners can be a bowel irritant as well (Skelly et al., 2006).

Older adults tend to have an insufficient intake of fluids and are more at risk to develop constipation. Sometimes, older adults reduce their fluid intake in an attempt to reduce micturition (see Chapter 42). In addition, in some individuals, an increased ingestion of milk or milk products may slow peristalsis and cause constipation (RNAO, 2011).

Physical Activity. Physical activity promotes peristalsis, whereas immobilization depresses peristalsis. Thus, early ambulation is encouraged as a patient's illness begins to resolve or as soon as possible after surgery to promote maintenance of peristalsis and thereby normal bowel elimination. Maintaining the tone of skeletal muscles used during defecation is important. Weakened abdominal and pelvic floor muscles impair the ability to increase intra-abdominal pressure and to control the external sphincter. Muscle tone may be weakened or lost as a result of long-term illness or neurological disease that impairs nerve transmission. Patients who experience these changes in the abdominal and pelvic floor muscles are at increased risk for constipation (Doughty, 2006; Schnelle et al., 2010).

Personal Bowel Elimination Habits. Personal bowel elimination habits can affect bowel function. Most individuals benefit from being able to use their own toilet facilities at a time that, for them, is both most effective and most convenient. A busy work schedule may prevent a person from going to the bathroom in response to the urge to defecate, thus disrupting regular habits and possibly causing constipation. A person should establish a regular time for bowel elimination (Doughty, 2006). In an institution, the nurse can facilitate this process by establishing toileting times (RNAO, 2011).

As discussed earlier, the ingestion of food is the main stimulus for mass peristalsis, which is known as the gastrocolic reflex. This reflex frequently leads to the need to defecate after a meal. The reflex is the strongest when the stomach is empty, and this is why breakfast is referred to as the "triggering meal" for a bowel movement for most people. The nurse can capitalize on this by offering assistance to toilet 15 to 20 minutes after a patient's breakfast.

Privacy. The patient's privacy must be maintained during bowel elimination. In hospital or long-term care settings, where patients may be in ward accommodation, maintaining visual, auditory, and olfactory privacy is important. Ignoring the call to stool because the patient is embarrassed can begin a cycle of constipation (RNAO, 2011).

Privacy and sensitivity must also be attended to when discussing bowel elimination with patients. Patients are very cautious about discussing bowel elimination because they are too embarrassed to broach the subject. It is the nurse's responsibility to ask about bowel elimination problems and create a therapeutic climate for the patient to voice their concerns (Bliss & Norton, 2010).

Figure 44-8 Critical thinking model for bowel elimination assessment.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgements require you to anticipate the information necessary, analyze the data, and make decisions regarding patient care. During your assessment (Figure 44-8), you must consider all elements that build toward making appropriate diagnoses and determining the contributing factors to the patient's issues.

To assess a patient's bowel elimination, you must integrate your knowledge from nursing and other disciplines to better understand the patient's response to bowel elimination interruptions. As emphasized earlier, patients often respond to disruptions in bowel elimination with embarrassment. Sensitivity on your part is essential.

Nursing Process and Bowel Elimination

❖ Assessment

Assessment for bowel elimination patterns and abnormalities includes a nursing health history, a physical assessment of the

abdomen, inspection of fecal characteristics, and a review of relevant test results. In addition, you need to determine the patient's perception of the problem and goals for treatment, medical history, pattern and types of fluid and food intake, chewing ability, medications, and recent illnesses and stressors.

Health History

The nursing health history provides a review of the patient's usual bowel patterns and habits. What a patient defines as "normal" may differ from factors and conditions that typically promote normal bowel elimination. You can determine the patient's problems by first identifying the normal and abnormal patterns and habits and then understanding the patient's perception of normal and abnormal regarding bowel elimination. Much of the nursing health history can be organized around the factors that affect bowel elimination:

- **Determination of the patient's usual bowel elimination pattern:** The frequency and time of day of the patient's bowel eliminations should be noted. Have the patient or caregiver complete a bowel elimination diary for a week to enable an accurate assessment of the typical bowel elimination pattern.
- **The patient's description of the usual stool characteristics:** The patient's description should indicate whether the stool is normally watery or formed, soft or hard; the typical colour; whether the stool floats or sinks; and whether blood is present. Ask the patient to describe the usual shape of the stool and the number of stools per day. The Bristol Stool Chart is a handy figure to show patients to determine the nature of their usual stools (see Figure 44-9).
- **Identification of routines followed to promote normal bowel elimination:** Examples of routines to promote bowel elimination are drinking hot liquids, eating specific foods, or taking time to defecate at a certain time of the day.
- **Assessment of the use of laxatives, suppositories, or enemas:** Assess whether the patient uses enemas, laxatives,

suppositories, or bulk-forming food additives in order to have a bowel movement. Ask the patient how often such an aid is used.

- **Assessment of cognitive abilities:** You must determine the patient's ability to understand the questions you pose. You may need to conduct a brief mental status examination. In situations where you are concerned, obtaining a corroborating history is critical.
- **Changes in appetite:** Note any changes in the patient's normal eating patterns and any change in weight (i.e., the amount lost or gained). If a change of weight has occurred, ask whether the weight change was planned, such as weight loss as a result of a low-calorie diet.
- **Diet history:** Determine the patient's dietary preferences. Assess the intake of fruits, vegetables, cereals, and breads and whether mealtimes are regular or irregular. In the case of the patient who is frail and living alone, determine whether acquiring food requires assistance (e.g., financial help, food preparation assistance, or transportation to a grocery store with a full selection of fresh fruits and vegetables).
- **Description of daily fluid intake:** Determine the type and amount of fluid consumed in a typical day. The patient might need to estimate the amount by using common household measurements.
- **History of surgery or illnesses affecting the GI tract:** This information can help to explain symptoms and to assess the patient's potential for maintaining or restoring a normal bowel elimination pattern. A patient's family history of gastrointestinal cancer is also relevant to your assessment.
- **Medication history:** Ask for a list of the patient's current medications. The medication history must include both prescribed and over-the-counter medications (e.g., laxatives, antacids, iron supplements, and analgesics) that might alter defecation or fecal characteristics. The community nurse should ask to see the medications.
- **Emotional state:** The patient's emotional state can significantly alter the frequency of defecation. During assessment, observe and ask directly about the patient's emotions and the presence of stress.
- **History of exercise:** Ask the patient to describe the type and amount of daily exercise and if there have been any recent changes to this activity level.
- **History of pain or discomfort:** Ask whether the patient has a history of abdominal or anal pain or pain with defecation. The quality, radiation, triggers, and location of pain may help to identify the source of the problem.
- **Environment and adaptive aids:** Patients have many different living arrangements. Where patients live may affect their toileting habits. If the patient is sharing living quarters, how many bathrooms are available? Does the patient have his or her own bathroom, or does the patient need to share the facilities and thus adjust the time the bathroom is used to accommodate other persons? If the patient lives alone, is he or she capable of ambulating to the toilet safely? If the patient is not independent in bowel management, who assists the patient and how? Does the patient use a bedpan, commode, or urinal? Does the patient wear incontinence products? Does the patient use a raised toilet seat or require grab bars?
- **Mobility and dexterity:** The patient's mobility and dexterity need to be evaluated to determine whether the patient needs assistive devices or personal assistance.

The Bristol Stool Form Scale

Figure 44-9 The Bristol Stool Chart **Source:** Bristol stool form guideline. Retrieved from <http://www.aboutconstipation.org/bristol.html>.

- **Presence and status of bowel diversions:** If the patient has an ostomy, assess the frequency of fecal drainage, the character of the feces, the appearance and condition of the stoma (e.g., the colour, the presence of swelling, and signs of irritation), the type of fecal collection device used, and the methods used to maintain the ostomy's function.

Physical Assessment

Your physical assessment (see Chapter 31) evaluates a patient's body systems and functions that are likely to be affected by the presence of bowel elimination problems.

Mouth. Your inspection of the mouth includes examining the patient's teeth, tongue, and gums. Poor dentition or poorly fitting dentures influence the ability to chew (see Chapter 42). Sores in the mouth can make eating not only difficult but also painful. A dry mouth may indicate dehydration (Jarvis et al., 2009).

Abdomen. Inspect all four abdominal quadrants for contour, shape, symmetry, and skin colour. Note masses, peristaltic waves, scars, venous patterns, stomas, and lesions. Normally, peristaltic waves are not visible; however, observable peristalsis can be a sign of intestinal obstruction.

Abdominal distension appears as an overall outward protuberance of the abdomen. Distension may be caused by intestinal gas, large tumours, or fluid in the peritoneal cavity. A distended abdomen feels tight, like a drum, and the skin appears taut, as if stretched (Jarvis et al., 2009).

Use percussion to detect lesions, fluid, or gas in the abdomen. Familiarity with the five percussion notes (see Chapter 31) permits identification of the underlying abdominal structures. Gas or flatulence creates a tympanic note. Masses, tumours, and fluid are dull to percussion.

Auscultate the abdomen with the stethoscope to assess bowel sounds in each quadrant (see Chapter 31). Normal bowel sounds occur every 5 to 15 seconds and last from one second to several seconds. While auscultating, note the character and frequency of the bowel sounds. An increase in pitch or a tinkling sound may be heard when the abdomen is distended. The lack of bowel sounds or the presence of

hypoactive sounds (fewer than five sounds per minute) occur when the patient has a paralytic ileus, such as after abdominal surgery. High-pitched and hyperactive bowel sounds (35 or more sounds per minute) occur when the small intestine is obstructed or when inflammatory disorders are present (Jarvis et al., 2009).

Gently palpate the abdomen for masses or areas of tenderness (see Chapter 31). During this procedure, encourage the patient to relax. Tensing of the abdominal muscles interferes with palpating underlying organs or masses (Jarvis et al., 2009).

Rectum. Inspect the area around the anus for lesions, discolourations, inflammation, and hemorrhoids. Abnormalities should be carefully recorded (see Chapter 31) (Jarvis et al., 2009).

Factors Related to Altered Patterns of Bowel Elimination

Age-Related Changes. Normal age-related changes affect bowel elimination (Table 44-1). In addition, many issues associated with aging can significantly alter bowel elimination, including polypharmacy, poor nutrition, life stressors, and comorbidities (Meiner, 2011).

Older adults also lose muscle tone in the perineal floor and the anal sphincter. Although the integrity of the external sphincter may remain intact, older adults may have difficulty controlling bowel evacuation and are at risk for incontinence. In addition, older adults may have a slowing of the nerve impulses to the anal region: some individuals are less aware of the need to defecate and, as a result, develop irregular bowel movements and are at risk for constipation (Meiner, 2011).

Infectious Disease. Microbial agents, including viruses, bacteria, and protozoa, can infect the GI tract. These infections can cause diarrhea and inflammatory or ulcerative changes in the small or large intestine. Most infections are spread by the oral-fecal route, through contaminated food or water.

The rotavirus is an example of a viral infection and is responsible for most nonbacterial food-borne epidemic gastroenteritis in all age groups. The virus is shed before and for days

► TABLE 44-1 Normal Age-Related Changes in the Gastrointestinal Tract

Portion of Gastrointestinal Tract	Functional or Physiological Change	Age-Related Causes
Mouth	Difficulty chewing and oral dryness	Medications can decrease saliva production. Taste buds atrophy.
Esophagus	Increase incidence of acid reflux	Reduced motility. Loss of muscle and ligament tone Decreased esophageal contractions.
Stomach	Decrease in acid secretions Not able to accommodate large amounts of food Increase risk of peptic ulcer disease, anemia, and stomach cancer Decrease in mucosal thickness	Degeneration of gastric mucosa Loss of parietal cells also leads to loss of the intrinsic factor, which is needed for vitamin B ₁₂ , iron, calcium, and folic acid absorption.
Small intestine	Decreased nutrient absorption	Atrophy of muscle and mucosal surfaces
Large intestine	Increased risk of diverticuli Increased occurrence of constipation Missed defecation signal	Atrophy of mucosa Atherosclerotic vascular changes Decrease in tone of internal and external sphincters

Source: Data from Meiner, S. (2011). *Gerontologic nursing* (4th ed.). St Louis, MO: Mosby.

after clinical illness. Very few infectious viruses are actually needed to cause disease. Rotavirus infection begins after about 24 hours' incubation and presents with mild to moderate fever and vomiting, followed by watery stools. Treatment is focused on preventing dehydration (Hannon & Porth, 2010).

Clostridium difficile (*C. difficile*) **colitis** is a bacterial infection associated with antibiotic therapy. Treatment with broad-spectrum antibiotics can lead to the disruption of the normal flora of the colon, creating colonization by *C. difficile* and the release of toxins that damage the mucosa and cause inflammation. The infection manifests with mild to moderate diarrhea and lower abdominal cramping. *C. difficile* is usually acquired in the hospital setting, where the organism is commonly found. Treatment includes immediate discontinuation of the antibiotic and in cases where symptoms are severe, treatment is aimed at eradication of *C. difficile* (Hannon & Porth, 2010).

Outbreaks of the highly contagious Norwalk virus are common in Canadian schools, hospitals, day care centres, and nursing homes. The Norwalk virus has been described as "the winter vomiting disease" and rapidly spreads to staff, students, and patients. When the Norwalk virus is detected, standard infection control procedures need to be implemented rapidly, accompanied by further precautions, such as isolation of the affected units, strict handwashing protocols, the wearing of gloves and gowns, and a thorough washing down of the affected units. When an outbreak occurs, the institution is frequently closed to visitors, and infected staff are required to remain off duty until they are symptom-free for 48 hours. In healthy individuals, symptoms last from 12 to 60 hours. The very young, older adults, and ill patients are at danger from dehydration and electrolyte imbalance (Conly & Johnston, 2003).

Irritable Bowel Syndrome. Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder with chronic intestinal symptoms that cannot be explained by structural or biochemical abnormalities. The symptoms of IBS can include abdominal pain, altered bowel function, flatulence, bloating, nausea, anorexia, and diarrhea. The hallmark symptom is abdominal pain that is relieved by defecation and accompanied by a change in the frequency or consistency of stools (Hannon & Porth, 2010).

IBS is related to diet, stress, and psychological factors and its onset may be triggered by a GI infection. The precise pathophysiology of IBS is not understood. Management is multimodal, based on the patient's most troublesome symptoms and includes counselling, dietary modifications, and medications (such as bulking agents, antispasmodics, and antidepressants) (Quartero et al., 2005). The nurse can support the patient with IBS by offering coaching on stress management and maintaining a high-fibre diet (Hannon & Porth, 2010).

Diabetes. Patients with diabetes frequently report problems with constipation and/or diarrhea due to GI autonomic neuropathy. Hyperglycemia can directly reduce or slow gastric contractions and the GI emptying rate. GI symptoms are more prevalent in patients with poor glycemic control. Symptoms can be improved by dietary changes, including reducing fats and increasing daily fibre intake (Bharucha et al., 2008; DUBY et al., 2004).

Pain. Normally, the act of defecation is painless. However, several conditions can result in discomfort, including hemorrhoids, rectal surgery, rectal fistulas, and abdominal surgery. In these instances, to avoid pain, the patient often suppresses

the urge to defecate. As a result, constipation and impaction may develop.

Pelvic Floor Trauma. Trauma to the pelvic floor muscles from pregnancy, labour and delivery, and aging can affect bowel elimination in women.

As pregnancy advances, the size of the fetus increases and pressure is exerted on the rectum. A temporary obstruction created by the fetus impairs the passage of feces. Slowing of peristalsis during the third trimester often leads to constipation. A pregnant woman's frequent straining during defecation or delivery can result in the formation of permanent hemorrhoids. Damage to the perineum extending to the anal sphincters during labour can also alter sphincter integrity (Doughty, 2006).

Older women, particularly those who have borne children, frequently develop loss of tone and weakening of the ligaments and muscles of the anterior and posterior vaginal walls. This condition can lead to cystocele (the dropping of the bladder into the vagina), rectocele (the pouching of the feces-filled rectum into the vagina), and sometimes complete prolapse of the uterus out of the vagina. Both of these conditions alter the anorectal angle and can inhibit complete evacuation (Doughty, 2006). Nurse Continence Advisors (i.e., registered nurses who are specially educated in continence care) treat these problems by educating patients about high-fibre diets and teaching pelvic floor muscle exercises, often referred to as Kegel exercises (Skelly et al., 2006).

Acute Illness, Surgery, and Anaesthesia. The GI system may be affected by any acute illness. Changes in the patient's fluid status, mobility patterns, nutrition, and sleep cycle can affect regular bowel habits. Surgical interventions on the GI tract affect bowel elimination, as will surgery on other systems, such as the musculoskeletal and cardiovascular systems.

The general anaesthetic agents used during surgery cause temporary cessation of peristalsis (see Chapter 48). Inhaled anaesthetic agents block the parasympathetic impulses to the enteric nervous system, and the stress of surgery stimulates the sympathetic nervous system. The anaesthetic's action slows or stops the integrated contractions. Pain control medication that contains opioids has the adverse effects of slowing mass peristalsis (or mass movement) and increasing the slow-mixing contractions and fluid absorption from the colon. Thus, following surgery, abdominal discomfort from intraluminal gas and constipation are frequent, and the surgeon's postoperative orders typically include bowel routine with laxatives and enemas if bowel movements do not occur within two to three days. Thus, you need to note whether and when the first bowel movement postsurgery occurs because the patient may require treatment for constipation. Early postoperative ambulation stimulates the evacuation of flatus, stimulates peristalsis, and alleviates abdominal pain (Lewis et al., 2010).

The patient who receives local or regional anaesthesia is less at risk for bowel elimination alterations because bowel activity may be affected minimally or not at all. Any surgery that involves direct manipulation of the bowel temporarily stops peristalsis. This condition, called **paralytic ileus**, usually lasts 24 to 48 hours. If the patient remains inactive or is unable to eat after surgery, return of normal bowel function may be further delayed (Lewis et al., 2010).

Enteral Feeding. Patients receiving enteral feeding will experience changes in bowel elimination. When the absorptive area of the small intestine is reduced, patients may receive

nutrition through enteral feeding administered by tube into the gastrointestinal tract. Enteral feeding contains nutrients that do not need further digestion to be rapidly absorbed by the diminished area of the intestine.

Patients receiving their nutrition through enteral feeding may experience diarrhea. This can be due to the feed running too quickly, medications, or an active infection (Lewis et al., 2010). Conversely, a patient could experience problems with constipation. This is usually related to the type of formula used, and a change to a high-fibre formula may resolve the constipation (Lewis et al., 2010). Again, medications the patient is taking must be examined for their effects on the GI system (Lewis et al., 2010).

Medications that Affect Elimination. Medication may have certain expected actions on the bowel; for example, some medications promote defecation and others control diarrhea. In addition, medications prescribed for acute and chronic conditions may have secondary effects on the patient's bowel elimination patterns (Table 44-2).

Laboratory Tests

Laboratory and diagnostic examinations yield useful information concerning bowel elimination problems (Table 44-3). Laboratory analysis of fecal contents can detect pathological conditions, such as tumours, bleeding, and infection.

Fecal Specimens. You are directly responsible for ensuring that fecal specimens are accurately obtained, properly labelled in appropriate containers, and transported to the laboratory on time. Institutions provide special containers for fecal specimens. Some tests require specimens to be placed in chemical preservatives.

Medical aseptic technique should be used during collection of stool specimens (see Chapter 32). Because approximately 25% of the solid portion of a stool is bacteria from the colon, wear disposable gloves when handling fecal specimens.

Hand hygiene is necessary for anyone who might come in contact with the specimen. The patient can often obtain the specimen if properly instructed. Explain that feces cannot be mixed with urine or water. For this reason, the patient must defecate into a clean, dry bedpan or a special container placed under the toilet seat.

Tests performed by the laboratory for occult (microscopic) blood in the stool and stool cultures require only a small sample. Collect about 2.5 cm of formed stool or 15 to 30 mL of liquid diarrhea stool. Tests for measuring the output of fecal fat require a three- to five-day collection of stool. All fecal material must be saved throughout the test period.

After obtaining a fecal specimen, label and tightly seal the container, complete the laboratory requisition forms, and record the specimen collections in the patient's medical record. Avoid delays in sending specimens to the laboratory because some tests, such as measurements for ova and parasites, require the stool to be warm. When stool specimens are allowed to stand at room temperature, bacteriological changes occur that can alter the test results.

A common laboratory test that can be done at home or at the patient's bedside is the **fecal occult blood test (FOBT)**, or guaiac test, which measures microscopic amounts of blood in the feces (Box 44-1). This test is useful as a diagnostic screening for colon cancer (Box 44-2). A single positive result does not confirm GI bleeding. The test should be repeated at least three times while the patient refrains from ingesting foods and medications that can cause false-positive results. For example,

► TABLE 44-2

Medications and the Gastrointestinal System

Medication	Action
Opioids	Increase the mixing action of segmentation contractions and slow the propulsive contractions, often resulting in constipation, nausea, vomiting, or anorexia (Lilley et al., 2011).
Anticholinergics (such as atropine)	Inhibit gastric acid secretion and depress gastrointestinal motility. Although anticholinergics are useful in treating hyperactive bowel disorders, they can cause constipation (Lilley et al., 2011).
Antibiotics	Frequently produce diarrhea by disrupting the normal bacterial flora in the gastrointestinal tract. Antibiotic use has been shown to promote infection with the highly contagious <i>C. difficile</i> , which has a high mortality rate in older adults. Concurrently taking a probiotic acidophilus supplement has been shown to reduce the incidence of diarrhea and to reduce the risk of <i>C. difficile</i> infections (McFarland, 2006).
Nonsteroidal anti-inflammatory drugs (such as acetylsalicylic acid)	Prostaglandin inhibitors are used to treat arthritis pain but can also promote gastrointestinal irritation that can range from dyspepsia to life-threatening hemorrhage (Lilley et al., 2011).
Histamine ₂ (H ₂) antagonists (such as ranitidine)	Reduce the secretion of hydrochloric acid and commonly used to treat many acid-related disorders. Suppress gastric acid secretion and may also predispose patients to GI infections (Lilley et al., 2011).
Proton pump inhibitors (such as omeprazole)	Can cause blackening of the stool and can lead to constipation (Lilley et al., 2011).
Iron	Can cause blackening of the stool and can lead to constipation (Lilley et al., 2011).
Calcium carbonate	Adverse GI effects include constipation, obstruction, nausea, vomiting, and flatulence (Lilley et al., 2011).

during the test period, the patient should avoid ingesting red meat, poultry, fish, some raw vegetables, vitamin C, aspirin, or other nonsteroidal anti-inflammatory medications that can cause false-positive results (Colon Cancer Check, 2011). Patients who receive anticoagulants or who have a bleeding disorder or a GI disorder known to cause bleeding (e.g., intestinal tumours, bowel inflammation, or ulcerations) should be regularly screened for fecal occult blood.

Fecal Characteristics. Inspection of fecal characteristics (Table 44-4) reveals information about the nature of bowel elimination alterations. Several factors can influence each characteristic. A key to assessment is knowing whether any recent changes have occurred. The patient can best provide this information during the health history assessment.

► TABLE 44-3

Laboratory and Diagnostic Tests for Bowel Function**Measurement****Interpretation****Laboratory Tests**

Total bilirubin	Increased levels of bilirubin may result from hepatobiliary diseases, obstructions in the bile duct, certain anemias, and reactions to blood transfusions.
Alkaline phosphatase	Elevated levels of alkaline phosphatase may indicate obstructive hepatobiliary diseases, hepatobiliary carcinomas, bone tumours, or healing fractures.
Amylase	Elevated levels of amylase may indicate abnormalities of the pancreas, such as inflammation, tumours, cholecystitis, necrotic bowel, and diabetic ketoacidosis.
Carcinoembryonic antigen (CEA)	The carcinoembryonic antigen is elevated in the presence of cancer, inflammation of the GI tract, or hepatobiliary organs.

Direct Visualization**Endoscopy**

A colonoscopy is a routine examination for persons 50 years of age and older. Normally the GI tract is free of polyps, tumours, inflammation, ulcers, hernias, obstruction, and ulcerations. If a lesion, such as a polyp, is identified, the physician removes the growth or a portion of the growth and sends it to pathology for analysis. If bleeding is present, the physician may attempt to coagulate the source. In some cases, the identification of an abnormality may indicate the need for follow-up surgery for the patient.

Indirect Visualization**X-ray with contrast medium**

An X-ray may identify the presence of acute abnormalities in the GI tract. A series of X-rays will allow for indirect visualization of the entire tract. The presence of tumours, ulcerations, inflammation, or other abnormalities may indicate the need for further diagnostic testing and medical or surgical intervention.

► BOX 44-1

Procedural Guideline**Measuring Fecal Occult Blood****Delegation Considerations:**

This skill can be delegated to unregulated care providers (UCPs). The nurse directs the UCP to report immediately if blood is detected. You assess the significance of the findings.

Equipment:

- Hemoccult test paper
- Wooden applicator
- Clean gloves
- Clean, dry container to collect sample

Procedure:

1. Explain to the patient the purpose of the test and how the patient can assist. Patients can collect their own specimens if possible. Specimen must be free of urine and toilet paper.
2. Perform hand hygiene.
3. Apply clean disposable gloves.
4. Obtain uncontaminated stool specimen.
5. Use the tip of the wooden applicator to obtain a small portion of a stool specimen. Ensure the specimen is free of toilet paper.
6. Open the flap of the hemoccult slide. Using the wooden applicator, thinly smear the stool in the first box of the guaiac paper. Apply a second fecal specimen from a different portion of the stool to the slide's second box (see Step 6 illustration).

Step 6 Application of the fecal specimen on guaiac paper.

7. Close the slide cover and send the sample to the laboratory per your institution's policies and procedures.
8. Wrap the wooden applicator in a paper towel. Remove gloves and discard in the proper receptacle.
9. Perform hand hygiene.
10. Record any unusual fecal characteristics.

Diagnostic Examinations

A variety of radiological and diagnostic tests may be ordered for the patient who experiences altered bowel elimination (Box 44-3). Visualization of GI structures may be made by either a direct or indirect approach. Each test has a prescribed preparation routine to empty the GI area under study to facilitate visualization. Many facilities use conscious sedation during these procedures. Be sure you understand the safety precautions involved in the use of this form of anaesthesia. In many institutions, special training is required. A crash cart must be

present at the bedside, and the patient must be monitored continuously with pulse oximetry and frequent vital signs, usually every 15 minutes during and immediately following the procedure. Check the agency policy regarding the use of sedation for these examinations (Pagana & Pagana, 2010).

Diagnostic Tests. Diagnostic examinations that involve visualization of GI structures often require that portions of the bowel be empty. The patient receives a prescribed bowel

preparation before the test. Usually, the patient is asked to drink a large volume (4 L) of a solution containing a nonabsorbable inert molecule, such as polyethylene glycol. Other medications, cathartics, or enemas may also be used. In addition, the patient is not allowed to eat or drink after midnight of the day preceding examinations such as a colonoscopy, endoscopy, or other testing that requires visualization of the lower GI tract. Following the diagnostic procedure, the patient may experience changes in bowel elimination, such as increased gas or loose stools. These changes will stop when the patient resumes a normal eating pattern (Pagana & Pagana, 2010).

❖ Nursing Diagnosis

Your assessment of the patient's bowel function reveals data that may indicate an actual or potential bowel elimination problem or a problem resulting from bowel elimination alterations. The concept map in Figure 44-10 depicts how the nursing diagnosis of constipation may be related to other diagnoses. In this example, a patient with cancer has developed constipation as a result of activity intolerance and imbalanced nutrition. Both conditions are a result of the patient's pain. Diagnoses that may apply to patients with bowel elimination problems include the following:

- *Bowel incontinence*
- *Constipation*
- *Risk for constipation*
- *Perceived constipation*
- *Diarrhea*

A patient's associated problems, such as body-image changes or skin breakdown, require interventions unrelated to bowel function impairment. In some instances, however, you need to direct as much attention to the associated problem as to the bowel elimination problem.

Your ability to identify the correct nursing diagnosis depends not only on the thoroughness of assessment but also on recognition of defining characteristics and factors that can

► BOX 44-2 Screening for Colon Cancer

Risk Factors

- Older than 50 years of age
- Family history of colorectal cancer (particularly parent, child, or sibling)
- History of inflammatory bowel disease (e.g., ulcerative colitis or Crohn's disease)
- High-fat and low-fibre diet
- Obesity
- Excessive alcohol consumption
- Smoking
- Physically inactive

Warning Signs

- Unexplained change in bowel patterns
- Rectal bleeding
- Unexplained weight loss
- Urgent need to empty bowel
- Unexplained stool incontinence

Screening Tests

- Fecal occult blood test (FOBT) at least every two years after age 50
- If patient has family history of colorectal cancer in first-degree relative or has symptoms, colonoscopy

Source: Colon Cancer Check. (2011). *Colon cancer check public information*. Retrieved from <http://health.gov.on.ca>.

► TABLE 44-4 Characteristics of Feces

Characteristic	Normal	Abnormal	Cause of Abnormality
Colour	Brown	White or clay	Absence of bile pigment, such as in obstructive jaundice
		Black or tarry (i.e., melena)	Iron ingestion or upper gastrointestinal bleeding
		Red	Lower gastrointestinal bleeding, hemorrhoids
		Pale with fat or frothy	Malabsorption of fat
		Mucus or pus	Spastic constipation, colitis, excessive straining
Odour	Pungent; affected by food type	Bloody mucus	Blood in feces, inflammation, infection, hemorrhoids
		Noxious change	Blood in feces or infection
		Liquid	Diarrhea, reduced absorption
Consistency	Soft, formed	Hard	Constipation
		More than three times a day or less than once a week	Hypomotility or hypermotility (multifactorial)
Frequency	Daily or two to three times weekly		
Shape	Resembles diameter of rectum	Narrow, pencil shaped	Anal or distal rectal carcinoma
Constituents	Undigested food, dead bacteria, fat, bile pigment, cells lining intestinal mucosa, water	Blood, pus, foreign bodies, mucus, worms	Internal bleeding, infection, swallowed objects, irritation, inflammation
		Excess fat	Malabsorption syndrome, enteritis, pancreatic disease, surgical resection of intestine

► BOX 44-3 Radiological and Diagnostic Tests

Flat Plate Radiography

- A simple X-ray film of the abdomen that requires no preparation.

Computerized Tomography Scan

- An X-ray examination of the body from many angles uses a scanner and is analyzed by a computer.
- The preparation may be either nothing by mouth (NPO) or no preparation.
- The patient must be informed of the need to lie very still. If claustrophobia is a problem, light sedation may be used.

Ultrasound Imaging

- Technique used to visualize abdomen and organs within.
- High-frequency sound waves echo off body organs to create a picture.
- The preparation depends on the organ to be visualized and may include either fasting or no preparation.

Upper Gastrointestinal Barium Swallow Esophagram

- An X-ray examination uses an opaque contrast medium (e.g., barium) to examine the structure and motility of the upper gastrointestinal tract, including the pharynx, esophagus, and stomach.
- The patient must be restricted to NPO after midnight the night before the examination.
- The patient must remove all jewellery and other metallic objects.
- After the test, the patient must increase fluids to facilitate passage and elimination of the barium.

Lower Gastrointestinal Barium Enema

- An X-ray examination uses an opaque contrast medium to examine the lower gastrointestinal tract.
- The preparation includes a bowel preparation or cathartic to empty any remaining stool particles.

Upper Gastrointestinal Endoscopy

- An endoscopic examination of the upper gastrointestinal tract allows a more direct visualization via a lighted fiberoptic tube.
- The preparation is similar to that of the upper gastrointestinal barium swallow.
- A light sedation is required.

Colonoscopy

- An endoscopic examination of the rectum and colon that uses a long, flexible tube (i.e., a colonoscope) inserted into the rectum.
- Bowel must be cleansed and free of fecal material.
- Light sedation is required.

Sigmoidoscopy

- An examination of the interior of the sigmoid colon.
- Preparation is similar to that of a colonoscopy.
- Light sedation is required.

Magnetic Resonance Imaging

- A noninvasive examination uses magnetic and radio waves to produce a picture of the inside of the body.
- Provides better contrast between normal and pathologic tissue than an ultrasound.
- The preparation is NPO four to six hours before examination.
- No metallic objects are allowed in the room, including metal objects on clothes.

impair bowel elimination (Box 44-4). You need to determine the patient's risk, and then institute measures to ensure maintenance of normal bowel function.

Common Bowel Elimination Problems

You might care for patients who have or are at risk for bowel elimination problems because of emotional stress (anxiety or depression), inflammatory diseases, prescribed therapy, disorders impairing defecation, or physiological changes in the GI tract, such as surgical alteration of intestinal structures.

Constipation. Constipation is a symptom, not a disease (Box 44-5). The signs of constipation vary among patients, but usually include infrequent bowel movements (fewer than three per week), difficult evacuation of feces, inability to defecate at will, and hard feces (Ginsberg et al., 2007). Common signs are abdominal pain and distension and a sensation of fullness and pressure in the rectum. Straining during defecation is also an associated sign. When intestinal motility slows, the fecal mass becomes exposed over time to the intestinal walls and most of the fecal water is absorbed. Little water is left to soften and lubricate the stool. Passage of a dry, hard stool may cause rectal pain (Ginsberg et al., 2007). Constipation is a common concern during acute hospital admissions for older adults (Box 44-6).

Constipation can be a significant hazard to health. Straining during defecation may cause problems to the patient who has recently undergone abdominal, gynecological, or rectal surgery.

The effort to pass a stool can cause sutures to separate, thereby reopening the wound. Patients who have a history of cardiovascular disease, diseases causing elevated intraocular pressure (glaucoma), and increased intracranial pressure should prevent constipation and avoid using the Valsalva manoeuvre. The Valsalva manoeuvre can be avoided by exhaling through the mouth during straining. Constipation also affects a person's quality of life (Bliss & Norton, 2010).

Patients may experience constipation as a result of medications they are taking. Medications that cause constipation include anticholinergics, antidepressants, antiemetics, antihistamines, antihypertensives, anti-Parkinson agents, antipsychotics, antacids containing aluminum, analgesics, NSAIDs; histamine-2 blockers, hypnotics, diuretics, sedatives, iron supplements, and opioids (RNAO, 2011).

Constipation can also occur in conjunction with the treatment of urinary conditions, as an adverse effect of the medication but also because individuals with urinary incontinence may reduce their fluid intake to reduce the frequency of their need to urinate (Ginsberg et al., 2007).

Impaction. Fecal impaction results from unrelieved constipation. Fecal impaction is a collection of hardened feces that are wedged in the rectum and cannot be expelled. In cases of severe impaction, the mass can extend into the sigmoid colon. Patients who are debilitated, confused, or unconscious are most at risk for impaction. They are too weak or are unaware of the need to defecate, or they may be so dehydrated that the

Figure 44-10 Concept map for a patient who has ovarian cancer with bone metastases and constipation.

► BOX 44-4 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Inspect the abdomen for shape, symmetry.	Distended abdomen.	Diarrhea related to gastrointestinal disorder.
Auscultate for bowel sounds.	Bowel sounds are hyperactive and audible without a stethoscope.	
Percuss for general tympany.	Hyperresonance is present with gaseous distension.	
Assess frequency of stools.	Patient reports having more than three loose bowel movements a day, accompanied by muscle cramps.	
Assess hydration status.	Loss of skin turgor and dry mucous membranes.	
Have the patient describe the pain, cramping, or any associated factors.	Pain is colicky in nature and spasmodic.	
Evaluate the perianal area for redness and irritation.	Breakdown of perianal tissues.	

Sources: Ackley, B., & Ladwig, G., (Eds.). (2011). *An evidence-based guide to planning care* (9th ed.). St Louis, MO: Mosby Elsevier; and Jarvis, C., Browne, A., MacDonald-Jenkins, J., & Luctkar-Flude, M. (Eds.). (2009). *Physical examination and health assessment* (1st Canadian ed.). Toronto: Elsevier Canada.

stool is too hard and too dry to pass. High intake of fibre or cellulose without accompanying fluids can increase the risk of impaction.

An obvious sign of impaction is the inability to pass a stool for several days, despite the repeated urge to defecate. A

continuous oozing of diarrhea stool may develop when the liquid portion of feces located higher in the colon seeps around the impacted mass. Loss of appetite (anorexia), nausea or vomiting, abdominal distension and cramping, and rectal pain may accompany the condition. If you suspect an impaction, you

► BOX 44-5 Common Causes of Constipation

- Ignoring the urge to defecate
- Sedentary lifestyle, including lengthy bed rest or lack of regular exercise
- A low-fibre diet high in animal fats (e.g., meats, dairy products, eggs) and refined sugars (e.g., rich desserts)
- A low noncaffeinated fluid intake
- Prolonged and overuse of laxatives
- Polypharmacy
- Comorbidities such as Parkinson's disease, multiple sclerosis, rheumatoid arthritis, chronic bowel diseases, depression, eating disorders, hypothyroidism, hypocalcemia, or hypokalemia
- Neurological conditions that block the nerve impulse to the colon (e.g., spinal cord injuries, tumours)

Sources: Ginsberg, D. A., Phillips, S. F., Wallace, J., & Josephson, K. L. (2007). Evaluating and managing constipation in the elderly. *Urologic Nursing*, 27, 191–200; and Registered Nurses' Association of Ontario. (2011). *Prevention of constipation in the older adult population*. Toronto: Registered Nurses' Association of Ontario.

can gently perform a digital examination of the rectum and palpate for the impacted mass.

Diarrhea. Diarrhea is an increase in the number of stools (several bowel movements per day) and the passage of liquid, unformed feces. Diarrhea can be acute or chronic. Diarrhea can be caused by infectious organisms (as discussed above), food intolerances, medications (including chemotherapy), or intestinal disease. Intestinal contents pass through the small and large intestine too quickly to allow the usual absorption of fluid and nutrients. Irritation within the colon can result in an increased mucus secretion. As a result, feces become watery and the patient may be unable to control the urge to defecate (Hannon & Porth, 2010).

Excess loss of colonic fluid can result in serious fluid, electrolyte, or acid–base imbalances. Older adults are particularly susceptible to complications associated with diarrhea (see Chapter 39). Repeated passage of diarrhea stools exposes the skin of the perineum and the buttocks to irritating intestinal contents; therefore, meticulous skin care and containment of fecal drainage is needed to prevent skin breakdown (see Chapter 37) (Hannon & Porth, 2010).

The aims of treatment are to remove the precipitating conditions and to slow peristalsis. Drugs that are opiumlike (such as loperamide) are used to decrease gastrointestinal motility and stimulate water and electrolyte absorption. Antidiarrheal medications should not be used with patients who have blood in their stool or a high fever, because they could risk worsening the disease. Antibiotics are used only when enteric pathogens have been identified (Hannon & Porth, 2010).

Communicable food-borne pathogens can also cause diarrhea. The risk of food-borne illnesses can be greatly reduced by handwashing after using the bathroom and before and after preparing foods, and by properly storing and preparing fresh produce and meats. When diarrhea is the result of a food-borne virus, the goal is usually to rid the system of the pathogen, not to slow peristalsis.

Incontinence. Fecal incontinence is the inability to control the passage of feces and gas from the anus. Fecal incontinence is devastating to patients and has a significant effect on functional, social, and psychological well-being (Bliss et al., 2004). The possible embarrassment of soiling clothes can lead

* BOX 44-6 RESEARCH HIGHLIGHT

Constipation in Older Adults During an Acute Hospital Stay

Research Focus

Bowel problems during hospitalization can be common and distressing in older adults. In some cases, hospital stays can be lengthened if constipation is not addressed. The majority of guidelines and research done on constipation in older adults focus on patients in a long-stay hospital or in long-term care. Very few studies have been done on factors that predict the onset of constipation in the acutely hospitalized older adult. Identifying factors that precipitate constipation during an acute hospital stay would facilitate starting a specific, preventative care plan for constipation early in an older adult's hospital stay.

Research Abstract

The purpose of the study by Cardin et al. (2009) was to identify any factors predicting the onset of constipation in the acutely hospitalized older patients. The goal was then to create an evidence-based identification of which patients need early preventative measures. The study involved 192 patients over the age of 67 who were consecutively admitted for various medical conditions to an acute care ward in an Italian hospital. All patients were interviewed upon arrival, and detailed information was collected about their physical health, mental status, dietary problems, medication use, and consistency of feces. Information on constipation and medication use during their hospital stay was also collected.

Evidence-Informed Practice

- Use of laxatives at home was a factor in constipation during the hospital stay.
- Satisfaction with bowel movements is reduced in patients who must stay in bed for lengthy periods of time during their hospitalization.
- Patients who have had cerebrovascular accidents are also more unsatisfied with their bowel movements during their hospital stay.
- Nurses working in acute care should assess their patients for at-home laxative use upon admission and put in place a plan to prevent constipation for patients who used laxatives at home, are likely will remain in bed for longer than two weeks, or who have had a cerebrovascular accident.

Reference: Cardin, F., Minicuci, N., Droghi, A. T., Inelmen, E. M., Sergi, G., & Terranova, O. (2009). Constipation in acutely hospitalized older patients. *Archives of Gerontology and Geriatrics*, 50, 277–281. doi:10.1016/j.archger.2009.04.007.

to self-imposed social isolation (Skelly et al., 2006). Contributing factors to fecal incontinence include diet, fluid intake (in particular, caffeine), alcohol, and nicotine (Skelly et al., 2006). Physical conditions that impair anal sphincter function, compliance, or control can cause incontinence. Additionally, patients without the cognitive awareness of the urge to defecate are at risk for incontinence (Skelly et al., 2006). Conditions that create frequent, loose, large-volume, watery stools are predispositions for fecal incontinence (Bliss et al., 2000). Fecal incontinence can be successfully managed and treated with nursing intervention (Box 44-7).

Flatulence. In most healthy individuals, 100 to 200 mL of gas is present in the GI tract. Gas in the upper GI tract may increase from the swallowing of air. Gas production in the colon occurs from bacteria digesting cellulose in the colon.

BOX 44-7 NURSING STORY

Fecal Incontinence Is a Treatable Condition

I often hear from patients that refer themselves to the Continence Care Clinic that they had been told that fecal incontinence was just something to “put up with” as they got older. No matter how many times I hear this from older adults, it still surprises me that, given the wealth of quality research on strategies to promote continence, many health care providers—and consequently the public—think nothing can be done. Attitudes like this prevent older adults from seeking help for this treatable condition. In fact, patients with fecal incontinence more frequently avoid seeking medical care than those with constipation (Siproudhis et al., 2006).

I recently had the privilege of working with a patient on regaining her fecal continence. She had been experiencing problems with constipation most of her adult life and recently, in her 80s, had begun to have difficulty with emptying and fecal soiling. Her bowel movements were unpredictable as to the time of day, and the consistency varied from a Type 1 on the Bristol Stool Chart to a Type 6. She had a low dietary fibre intake because she felt too much fibre would exacerbate her condition (a common myth), and she drank mostly tea during the day. She took more than eight medications for other comorbidities, including an osmotic laxative.

Working together, we determined that the contributing factors to her fecal incontinence were low fluid intake, low dietary fibre, lack of bowel routine, polypharmacy, and a weak pelvic floor. Our mutually established conservative plan included drinking at least four to five 8-ounce glasses of water over the course of the day, gradually increasing her dietary fibre with the goal over time to achieve about 25 mg of fibre per day, limiting her caffeine intake to one to two cups a day, and allowing time after her morning meal to sit comfortably to have a bowel movement.

Gradually, over the next 12 weeks, with support and coaching, my patient successfully eliminated her fecal incontinence. She was so grateful for my support and remarked at what a positive difference being continent made to her quality of life and self-esteem. She was so relieved to be able to go about her daily activities without worrying about whether she would have an embarrassing accident. These successes make my work as a Nurse Continence Advisor so rewarding.

As gas accumulates in the lumen of the intestines, the bowel wall stretches and distends, resulting in **flatulence**. Flatulence is a common cause of abdominal fullness, pain, and cramping. Normally, intestinal gas escapes through the mouth (belching) or the anus (passing of flatus). For a person eating a normal diet, 50 to 500 mL of gas is passed 10 to 15 times a day. However, if intestinal motility is reduced as a result of the effects of opiates, general anaesthetics, abdominal surgery, or immobilization, flatulence can become severe enough to cause abdominal distension and severe, sharp pain (Lewis et al., 2010).

Hemorrhoids. Hemorrhoids are dilated, engorged veins in the lining of the rectum. They are either external or internal. External hemorrhoids are clearly visible as protrusions of skin. If the underlying vein is hardened, a purplish discoloration (i.e., thrombosis) may be visible. This condition causes increased pain, and the hemorrhoid may need to be excised. Internal hemorrhoids have an outer mucous membrane. Increased venous pressure as a result of pregnancy, heart failure, chronic liver disease, or straining at defecation can cause hemorrhoids. The presence of hemorrhoids is frequently accompanied by fecal soiling of undergarments and irritation

Figure 44-11 Critical thinking model for bowel elimination planning.

of the distended veins by overly vigorous cleaning of the anus. Meticulous cleaning following a bowel movement may reduce the possibility of irritation (Lewis et al., 2010).

❖Planning

During the planning of care, you synthesize information from multiple resources (Figure 44-11). Critical thinking ensures that the plan of care integrates all you know about the patient and the clinical problem. You must rely on professional standards. The guidelines on incontinence (see Chapter 43) can assist you in protecting the patient's skin, promoting continence, and reducing the embarrassment associated with incontinence. In addition, the Agency for Health Care Policy and Research (AHCPR), the Registered Nurses' Association of Ontario (RNAO), and the Canadian Association of Wound Care (CAWC) have guidelines on the reduction of pressure ulcers that also assist in developing care for patients with bowel incontinence (see Chapter 46).

Goals and Outcomes

You and the patient establish goals and outcomes by incorporating the patient's bowel elimination habits or routines as much as possible and by reinforcing routines that promote health. You also consider preexisting health concerns. For example, if the patient is at risk for the worsening of heart failure, an outcome of increased fluid intake must be tailored to the patient's cardiac function and ability to safely handle the increased fluid. For another example, if the patient's bowel habits caused the elimination problem, you can help the patient to learn new bowel habits. The overall goal of returning the patient to a normal bowel elimination pattern may include the following outcomes:

- The patient practises regular defecation habits.
- The patient lists the proper fluid and food intake needed to achieve regular bowel elimination.
- The patient implements a regular exercise program.
- The patient reports daily passage of soft, formed brown stool.
- The patient does not report any discomfort associated with defecation.

Setting Priorities

Defecation patterns vary among individuals. For this reason, you and the patient must work together closely to plan effective interventions (see Box 44-8). A realistic time frame to establish a normal defecation pattern for one patient might differ for another patient. For the patient who has a new ostomy as the result of newly diagnosed cancer, the priority of coping with cancer and its treatment may precede the patient's need to independently manage the bowel diversion. For another patient, however, when a bowel diversion is necessary, coping with the changes in body image may become a high priority for both the patient and the patient's family.

Continuity of Care

When patients are disabled or debilitated by illness, you need to include the patient's family in the plan of care. Family members often have the same bowel elimination habits as the patient. Thus, teaching both the patient and the patient's family is an important part of the care plan. Other health team members, such as dietitians and enterostomal therapist (ET) nurses, can be valuable resources. When patients require surgical intervention, a critical pathway may be used to coordinate the activities of the multidisciplinary health care team.

The patient who has alterations in bowel elimination will require intervention from many members of the health care team. Certain tasks, such as assisting patients onto the bedpan or bedside commode, are appropriate to delegate to unregulated care providers (UCPs). Remind the UCP to report any abnormal findings or difficulties encountered during the bowel elimination process. Non-nursing personnel perform many of the diagnostic tests used to evaluate the gastrointestinal system. You must maintain ongoing communication with these caregivers to ensure that the patient's safety, needs, wants, and concerns are addressed.

Implementation

The success of your interventions depends on improving the patient's and the family members' understanding of bowel elimination. In the home, hospital, or long-term care facility,

patients capable of learning can be taught effective bowel habits.

Teach the patient and the patient's family about proper diet, adequate fluid intake, and factors that stimulate or slow peristalsis, such as emotional stress. The patient should also learn the importance of establishing regular bowel routines, participating in regular exercise, and taking appropriate measures when bowel elimination problems develop.

Patient Expectations

Patients expect you to answer all their questions regarding diagnostic tests and the preparation for those tests. Patients will be concerned about discomfort and exposure. Fear of losing control of their bowel elimination is especially worrisome. Patients need reassurance that their needs will be met and that you are supportive. Patients expect a knowledgeable nurse who can teach them methods of promoting and maintaining a normal bowel elimination pattern.

Management of Bowel Elimination

One of the most important habits you can encourage patients to establish is a daily bowel routine that includes adequate fluid and food intake as well as regular exercise. The urge to defecate usually occurs within an hour following a meal, after breakfast being the most common time for most individuals. Having access to a bathroom, privacy, and a comfortable seated position are all factors in the routine. Many patients have their established routines for defecation at home, which can become disrupted if they are ill. In a hospital or long-term care facility, ensure that treatment routines do not interfere with the patient's bowel elimination routine. The provision of privacy is important to maintain. When a patient shares the room with other patients, pull the curtain around the area so the patient can relax, with the knowledge that interruptions will not occur. The call light should always be placed within the patient's reach. Bathroom doors should be closed, although you may stand close by in case the patient needs assistance.

Maintenance of Proper Fluid and Food Intake. Daily fluid intake should be between 1500 and 2000 mL per day of noncaffeinated beverages. Dietary fibre intake should be from 25 to 30 g per day. In choosing a diet to promote normal bowel elimination, you need to consider the frequency of defecation, the characteristics of the feces, and the types of foods that impair or promote defecation. The patient with frequent constipation or impaction requires an increased intake of high-fibre foods and more fluids. The patient needs to understand that diet therapy is only one factor to consider and may not give immediate relief from problems such as constipation.

Many evidence-informed interventions are available to reduce the risk of constipation (Box 44-9) (RNAO, 2011).

If diarrhea is a problem, then foods with a low-fibre content such as applesauce, bananas, and rice will reduce gastric upset or abdominal cramping. Diarrhea caused by illness can be debilitating. If the patient cannot tolerate foods or liquids orally, intravenous therapy (with potassium supplements) is necessary. The patient returns to a normal diet slowly, often beginning with fluids. Excessively hot or cold fluids stimulate peristalsis, thereby causing abdominal cramps and further diarrhea. As the tolerance to liquids improves, solid foods are ordered. Following a severe diarrheal episode, milk products may need to be withheld until the enterocyte population has matured. Milk products may have the effect of perpetuating the diarrhea.

► BOX 44-8 NURSING CARE PLAN

Constipation

Assessment

Javier is a nurse who visits Larry at his home on a cattle ranch. Larry lives 40 km from town. He is 22 years old and had surgery six days ago for repair of a broken right leg. Larry tells Javier, "I just don't feel good."

Assessment Activities

Ask Larry about his recent bowel elimination patterns over the last five days.

Review Larry's medication.

Review Larry's dietary intake over the past day.

Ask about any nausea or vomiting.

Auscultate the abdomen.

Palpate the abdomen.

Findings and Defining Characteristics

Larry has not had a bowel movement since he left the hospital four days ago and he feels like his abdomen is tight and sore.

Larry has been prescribed opioids for pain. He is taking them regularly, as prescribed.

Larry has eaten eggs, bacon, and toast for breakfast and soup for lunch. For supper, Larry had chicken, rice, and corn. He drinks about six cups of coffee each day, no water, but will drink a cola.

Larry has not felt nauseated.

Decreased bowel sounds are auscultated throughout all four abdominal quadrants.

While Javier is palpating Larry's abdomen, Larry tells Javier, "It really hurts." On palpation, the left lower quadrant is tender and firm.

Nursing Diagnosis: Constipation related to opiate-containing pain medication and decreased fibre intake.

Planning

Goals (Nursing Outcomes Classification)*

Bowel Elimination

Larry will establish normal defecation.

Larry will voice relief from constipation.

Expected Outcomes

Larry will drink at least 1500 mL of fluid over the next eight hours.

Larry will report passage of soft stool without straining within 24 hours.

Nutritional Status: Food and Fluid Intake

Larry will identify measures to prevent constipation.

Larry will increase the amount of daily exercise.

Larry will increase the fibre content of his diet.

*Outcome classification labels from Ackley, B., & Ladwig, G. (Eds.). (2011). *An evidence-based guide to planning care* (9th ed.). St Louis, MO: Mosby Elsevier.

Interventions

Constipation or Impaction Management

Encourage fluid intake of fruit juice, water, and other appropriate fluids.

Encourage activity within the limits of Larry's mobility regimen.

Add bran flakes or bran to the diet.

Provide laxative or stool softeners as ordered.

Provide a private atmosphere for bowel elimination.

Rationale

Adequate fluid intake is necessary to prevent hard, dry stool.

Even minimal activity (such as leg lifts) increases peristalsis.

The number of bowel movements is increased with consumption of bran (Bliss et al., 2001).

Medications can soften the stool and prevent straining (Lilley et al., 2011).

Patients should feel relaxed when moving their bowels.

Continued

► BOX 44-8 NURSING CARE PLAN—cont'd

Evaluation

Nursing Actions

Ask Larry to identify foods high in fibre.

Ask Larry to plan menus to increase fibre.

Ask Larry about increased activity.

Observe Larry's subsequent stool for characteristics such as consistency and colour.

Patient Response and Findings

Larry is able to correctly identify high-fibre foods. Review of the 24-hour diet diary shows Larry is selecting high-fibre, low-fat foods.

Review of the 24-hour diet diary shows meals planned with high-fibre content. Larry reviews his shopping list, which includes bran, oat, and fruit products.

Larry states that he has not changed his level of activity.

Stools are now every 24 to 48 hours. Larry states he does not "feel regular." The abdomen is soft and nondistended. Stools are formed and hard, and Larry reports straining.

Achievement of Outcome

Larry is making excellent progress in introducing high-fibre and low-fat foods into his diet.

Larry is knowledgeable about fibre content and purchases foods that are high in fibre.

Larry has not increased his level of activity and needs to continue to work on increasing his physical activity.

Larry has not achieved passage of a regular, formed stool.

* BOX 44-9 EVIDENCE-INFORMED PRACTICE GUIDELINE

Prevention of Constipation in the Older Adult Population

- Fluid intake of at least 1500 to 2000 mL per day is recommended. The preferred fluid is water because it is sodium-free and calorie-free. The patient may also benefit from drinking one to two glasses of fruit juice.
- Coffee, tea, and alcohol should be avoided because of their diuretic properties.
- A high-fibre diet (25 to 30 g/day) reduces constipation; fibre that passes through the colon acts as a sponge. As a result, bulkier and softer stools develop. In addition, the waste moves through the body more easily and results in more regular bowel movements. A high-fibre diet is not recommended for individuals who are immobile or who do not consume at least 1.5 L of fluid per day.
- The most beneficial means to prevent constipation is a combination of insoluble and soluble fibre (e.g., bran, fruits, and vegetables).
- Physical activity in combination with adequate fluid intake and a high-fibre diet is beneficial in the management of constipation. For patients who are fully mobile, walking once or twice a day for 15 to 20 minutes is sufficient.
- For individuals who are unable to walk, recommend chair or bed exercises, such as the pelvic tilt, low trunk rotation, and single leg lifts.
- Laxatives should be used with caution. If laxatives are necessary, a stepwise progression is recommended: first bulk-forming laxatives, followed by stool softeners, osmotics, stimulants, suppositories, and enemas as a last resort.

Source: Adapted from Registered Nurses' Association of Ontario. (2011). *Prevention of constipation in the older adult population*. Toronto: Registered Nurses' Association of Ontario.

Promotion of Regular Exercise. A daily exercise program helps prevent bowel elimination problems. Walking, riding a stationary bicycle, or swimming stimulates peristalsis. Patients who are sedentary at work are most in need of regular exercise. For patients with mobility problems, such as arthritis, a passive exercise program may be helpful.

For a patient who is temporarily immobilized, you should attempt ambulation of the patient as soon as possible. If the condition permits, assist a postoperative patient in walking to a chair on the evening of the day of surgery. The patient should walk farther each day.

Exercises can help bedridden patients to more comfortably use a bedpan. The patient can practise the following exercises:

- Lie supine; tighten the abdominal muscles as though pushing them to the floor. Hold them tight to the count of three; relax. Repeat 5 to 10 times as tolerated.
- Flex and contract the thigh muscles by raising one knee slowly toward the chest. Repeat for each leg at least five times and increase the frequency as tolerated.

Bowel Retraining. The patient with incontinence is unable to maintain bowel control. A **bowel retraining** program can help some patients achieve normal defecation, especially those who still have some neuromuscular control.

The training program involves setting up a daily routine. By attempting to defecate at the same time each day and by using measures that promote defecation, the patient gains control of the bowel reflexes. The program requires time, patience, and consistency. Be sure to determine the patient's physical readiness and ability to benefit from bowel training. A successful program includes the following:

- Assessing the patient's normal bowel elimination pattern and recording times when the patient is incontinent
- Choosing a time based on the patient's pattern to initiate defecation-control measures by assisting the patient to the toilet at the designated time
- Offering a hot drink (e.g., tea), fruit juice (e.g., prune juice), or another fluid that normally stimulates peristalsis for the patient before the selected defecation time

- Instructing the patient to avoid medications such as analgesics, which may increase constipation
- Providing privacy and setting a time limit for the defecation (15 to 20 minutes)
- Instructing the patient to lean forward at the hips while sitting on the toilet, to apply manual pressure with the hands over the abdomen, and to bear down but not to strain to stimulate the colon to empty
- Refraining from making critical remarks or conveying frustration if the patient is unable to defecate
- Providing regular meals with adequate fluids and fibre (Bliss and Norton, 2010).
- Maintaining normal exercise within the patient's physical ability.

Hemorrhoids. Many patients experience discomfort from alterations in their bowel elimination. Pain results when hemorrhoid tissues are directly irritated. The primary goal for the patient with hemorrhoids is to have soft-formed, painless bowel movements. Proper diet, fluids, and regular exercise improve the likelihood of the stools being soft. If the patient becomes constipated, passage of hard stools may cause bleeding and irritation. Local heat provides temporary relief to swollen hemorrhoids. A sitz bath is the most effective means of heat application.

Maintenance of Skin Integrity. The patient with diarrhea or fecal incontinence is at risk for skin breakdown when fecal contents remain on the skin. Liquid stool is usually acidic and contains digestive enzymes. Irritation from repeated wiping with toilet tissue aggravates the breakdown of skin. Bathing the skin after soiling helps but may result in more breakdown unless the skin is thoroughly dried.

When caring for an incontinent patient who is unable to ask for assistance, you should check often for defecation. The anal areas can be protected with barrier cream that holds moisture in the skin to prevent drying and cracking. Yeast infections of the skin can develop easily. Several powdered antifungal agents are effective against yeast. Baby powder or cornstarch should not be used because they have no medicinal properties and they frequently cake on the skin, which makes them difficult to remove.

Medications. Medications may be used to initiate and facilitate bowel elimination. Cathartics, laxatives, and occasionally an enema are used to control constipation, whereas antidiarrheal preparations assist the patient in resolving diarrhea. All these medications are available over the counter; stronger preparations are available through prescriptions. Patients must be cautioned not to use these over-the-counter medications on a prolonged basis without consulting their health care provider.

Laxatives are defined as products that stimulate evacuation of the formed stool from the rectum, whereas **cathartics** are defined as products that evacuate unformed and usually watery fecal material from the entire colon. Laxatives are thus milder in action than cathartics. When used correctly, laxatives and cathartics safely maintain normal bowel elimination patterns; however, chronic use of cathartics causes the large intestine to lose muscle tone and to become less responsive to stimulation by laxatives. Laxative overuse can also cause serious diarrhea that can lead to dehydration and electrolyte depletion. Mineral oil, a common laxative, decreases fat-soluble vitamin absorption. Laxatives can influence the efficacy of other medications by altering the transit time (i.e., the

time the medication remains in the GI tract and is available for absorption).

safety alert Excessive use of laxatives, enemas, or bulk-forming agents increases the patient's risk for diarrhea and abnormal bowel elimination and destroys the patient's normal defecation reflex. In addition, the patient may develop an altered absorption of nutrients, fluid and electrolyte imbalances, and generalized weakness. When these symptoms occur in chronically ill or older adult patients, they may result in an increased risk for falls and other injuries.

Cathartics and Laxatives. A patient is often unable to defecate normally because of pain, constipation, or impaction. Cathartics and laxatives provide the short-term action of emptying the bowel. They are also used in bowel evacuation for patients undergoing GI tests and abdominal surgery. Although the terms *cathartic* and *laxative* are often used interchangeably, cathartics have a stronger effect on the intestines. Five types of laxatives and cathartics are available (Table 44-5).

Cathartics and laxatives are available in oral, tablet, and powder suppository dosage forms (see Chapter 33). Although the oral route is most commonly used, cathartics that are prepared as suppositories are more effective because of their stimulant effect on the rectal mucosa. Cathartic suppositories such as bisacodyl (Dulcolax) can act within 30 minutes. Older adults who use Dulcolax often have a strong, sudden urge to defecate.

Electrolyte Balance and Antidiarrheal Agents. For patients with diarrhea, frequent passage of liquid stools becomes a problem. When a person has secretory diarrhea, cells at the base of the villi secrete massive amounts of fluid into the lumen of the small intestine. However, the tip of the villi can still absorb sugars and fluids. Therefore, diarrhea can quickly lead to serious electrolyte imbalances, particularly in infants and children (see Chapter 39). Therefore, the first course of action is to immediately replace fluids by mouth. Fluids with adequate electrolyte content (e.g., Pedialyte and Gastrolyte) are a wise choice. In developing countries without a safe water supply or during epidemics of infectious diarrhea (e.g., cholera), millions of lives have been saved by using a cheap, safe, and simple method of replacing water and salts lost through diarrhea. This method, known as oral rehydration therapy (ORT), involves mixing a very low-cost package of salts (sodium, potassium chloride, citrate or bicarbonate, and glucose) with boiled water.

Many patients will use over-the-counter agents, such as Imodium, to relieve common diarrhea. However, the most effective antidiarrheal agents are prescriptive opiates, such as codeine phosphate, opium tincture (Paregoric), and diphenoxylate (Lomotil). Opiates inhibit the peristaltic waves that move feces forward but also increase the segmental contractions that mix intestinal contents and expose the contents to the mucosal absorbing surface. The further effect of opiates on increasing the absorption of sodium and water also dries out the feces. As a result, more water is absorbed by the colonic mucosa. These antidiarrheal agents should be used with caution because opiates are habit forming.

Enemas. An **enema** is the instillation of a solution into the rectum and sigmoid colon. The primary reason for using an enema is to promote defecation by stimulating peristalsis. The volume of fluid instilled breaks up the fecal mass, stretches the rectal wall, and initiates the defecation reflex. Enemas are

► **TABLE 44-5** Common Types of Laxatives and Cathartics

Agents and Brand Names	Action	Indications	Risks
Bulk Forming			
Methylcellulose (Benefibre)	The high-fibre content absorbs water and increases solid intestinal bulk.	These agents are the least irritating, most natural, and safest cathartics. These agents are the drugs of choice for treating chronic constipation (e.g., during pregnancy or as the result of a low-residue diet).	These agents can cause obstruction if not mixed with at least 240 mL of water or juice and swallowed quickly.
Psyllium (Metamucil)	These agents stretch the intestinal wall to stimulate peristalsis.	These agents may also be used to relieve mild, watery diarrhea.	Use caution with bulk-forming laxatives that also contain stimulants. These agents are not used in patients for whom large fluid intake is contraindicated.
Emollient or Wetting			
Docusate sodium (Colace) Docusate calcium (Surfak)	Stool softeners are detergents that lower the surface tension of feces, allowing water and fat to penetrate. They may increase the secretion of water by the intestines.	These agents are used for short-term therapy to relieve straining on defecation. These agents would be beneficial for patients who have hemorrhoids, have undergone perianal surgery, are pregnant, or are recovering from myocardial infarction.	These agents are of little value for treatment of chronic constipation.
Saline			
Magnesium citrate or citrate of magnesia (Citromag)	These agents contain a salt preparation that is not absorbed by the intestines.	These agents are used only for acute emptying of the bowel (e.g., as a preparation for endoscopic examination, in cases of suspected poisoning, or to treat acute constipation).	These agents are not used for long-term management of constipation.
Magnesium hydroxide (Milk of Magnesia)	The osmotic effect increases pressure in the bowel to act as stimulant for peristalsis.		These agents are contraindicated for patients with kidney dysfunction (to avoid a toxic buildup of magnesium).
Sodium phosphate (Fleet Enema)	Sodium phosphate		Phosphate salts are not used for patients on fluid restriction.
Stimulant Cathartics			
Bisacodyl (Dulcolax)	These agents irritate the intestinal mucosa to increase motility.	These agents may be used to prepare the bowel for diagnostic procedures.	These agents may cause severe cramping.
Castor oil (Neoloid, Purge)	These agents decrease absorption in the small bowel and colon.		These agents are not for long-term use.
Phenolphthalein (Doxidan, Correctol, Ex-Lax)	Phenolphthalein and danthron may cause pink or red urine.		
Lubricants			
Mineral oil (Haley's M-O, Petrogalar Plain)	These agents coat the fecal contents, which allows for easier passage of the stool. These agents reduce water absorption in the colon.	These agents are used to prevent straining on defecation (e.g., for patients who have hemorrhoids and for those who are recovering from perianal surgery).	These agents decrease the absorption of fat-soluble vitamins (A, D, E, and K). These agents can cause a dangerous form of pneumonia if aspirated into the lungs. Mineral oil when taken with emollients can increase the risk for fat emboli.

Source: Lilley, L. L., Harrington, S., Snyder, J. S., & Swart, B. (2011). *Pharmacology for Canadian health care practice* (2nd Canadian ed.). Toronto: Elsevier Canada.

also used as a vehicle for administering medications that exert a local effect on rectal mucosa.

The most common use for an enema is temporary relief of constipation. Other indications include removing impacted feces; beginning a program of bowel training; and emptying the bowel before diagnostic tests, surgery, or childbirth.

Cleansing Enemas. Cleansing enemas promote the complete evacuation of feces from the colon. They act by stimulating peristalsis through the infusion of a large volume of solution or through local irritation of the colon's mucosa. Solutions used in cleansing enemas include tap water, normal saline, low-volume hypertonic saline, and soapsuds solution. Each solution exerts a different osmotic effect to move fluids between the colon and the interstitial spaces beyond the intestinal wall. Infants and children should receive only normal saline because they are at risk for fluid imbalance.

A physician may order a high or low cleansing enema. The terms *high* and *low* refer to the height from which, and hence the pressure with which, the fluid is delivered. High enemas are given to cleanse the entire colon. After the enema is infused, the patient is asked to turn from the left lateral position to the dorsal recumbent position and to the right lateral position. The position change ensures that fluid reaches all of the large intestine. A low enema cleanses only the rectum and the sigmoid colon.

Tap Water. Tap water is hypotonic and exerts a lower osmotic pressure than that of fluid in interstitial spaces. After infusion into the colon, tap water escapes from the bowel lumen into the interstitial spaces. The net movement of water is low. The infused volume stimulates defecation before large amounts of water leave the bowel. Tap water enemas should not be repeated because water toxicity or circulatory overload can develop if large amounts of water are absorbed.

Normal Saline. Physiologically, normal saline is the safest solution to use because it exerts the same osmotic pressure as that of fluids in the interstitial spaces surrounding the bowel. The volume of infused saline stimulates peristalsis. Unlike tap water enemas, saline enemas do not create the danger of excess fluid absorption.

Hypertonic Solutions. Hypertonic solutions infused into the bowel exert osmotic pressure that pulls fluids out of the interstitial spaces. The colon fills with fluid, and the resultant distension promotes defecation. Patients unable to tolerate large volumes of fluid benefit most from this type of enema, which is, by design, low volume. Contraindications for this type of enema are patients who are dehydrated and young infants. A hypertonic solution of 120 to 180 mL is usually effective. The commercially prepared Fleet Enema is the most commonly used hypertonic solution.

Soapsuds. Soapsuds may be added to tap water or saline to create the effect of intestinal irritation to stimulate peristalsis. Only pure castile soap is safe to use. A liquid form of castile soap is included in most soapsuds enema kits. Harsh soaps or detergents can cause serious bowel inflammation.

Oil-Retention Enemas. Oil-retention enemas lubricate the rectum and colon. The feces absorb the oil and become softer and easier to pass. To enhance the action of the oil, the patient retains the enema for several hours if possible.

Other Types of Enemas. Carminative enemas provide relief from gaseous distension. Use of a carminative enema improves the ability to pass flatus. An example of a carminative enema is MGW solution, which contains 30 mL of magnesium, 60 mL of glycerine, and 90 mL of water.

Medicated enemas contain drugs. An example is sodium polystyrene sulphonate (Kayexalate), which is used to treat patients with dangerously high serum potassium levels. This drug contains a resin that exchanges sodium ions for potassium ions in the large intestine. Another medicated enema is neomycin solution, which is an antibiotic used to reduce bacteria in the colon before bowel surgery.

Enema Administration. Enemas are administered in either commercially packaged, disposable units or with reusable equipment prepared before use. Sterile technique is unnecessary because the colon normally contains bacteria; however, gloves should be worn to prevent the transmission of fecal microorganisms.

You should explain the procedure to the patient, including the position to assume, precautions to take to avoid discomfort, and the length of time necessary to retain the solution before defecation. If the patient is to receive the enema at home, explain the procedure to a family member.

Often the physician orders "enemas until clear." This order means that the enema is to be repeated until the patient passes fluid that is clear and contains no fecal material. As many as three enemas may be necessary, but you should caution the patient against more than three enemas. Excess enema use seriously depletes fluids and electrolytes. If the enema fails to return a clear solution after three times (check agency policy on the maximum number of enemas permitted) or if the patient seems to not be tolerating the rigors of repeated enemas, notify the physician.

Giving an enema to a patient who is unable to contract the external sphincter can pose difficulties. In these cases, give the enema with the patient positioned on the bedpan. Giving the enema with the patient sitting on the toilet is unsafe because the curved rectal tubing can abrade the rectal wall. Skill 44-1 outlines the steps for an enema administration.

safety alert For patients with an impaction, the fecal mass may be too large to be passed voluntarily. If enemas fail, you may consider breaking up the fecal mass with your finger and removing it in sections (Box 44-10). The procedure will be very uncomfortable for the patient. Excess rectal manipulation may cause irritation to the mucosa, bleeding, perforation of the bowel wall, and stimulation of the vagus nerve, which results in a reflex slowing of the heart rate. Because of the procedure's potential complications, a physician's order is necessary for you to remove a fecal impaction.

Surgical Management of Bowel Elimination

Inserting and Maintaining a Nasogastric Tube. A patient's condition or situation may warrant special interventions to decompress the GI tract. Such conditions include surgery, infections of the GI tract, trauma to the GI tract, and the absence of peristalsis.

A nasogastric (NG) tube is a pliable tube that is inserted through the patient's nasopharynx into the stomach. The tube has a hollow lumen that allows removal of gastric secretions and introduction of solutions into the stomach. Nasogastric intubation has several purposes (Table 44-6).

The Levin and Salem sump tubes are the most common tubes used for stomach decompression. The Levin tube is a single-lumen tube with holes near the tip. A sump tube may be connected to either a drainage bag or an intermittent suction device to drain stomach secretions.

► SKILL 44-1 Administering a Cleansing Enema

Delegation Considerations

The skill of administering an enema can be delegated to unregulated care providers (UCPs). You have the responsibility to assess the patient for specific considerations, such as his or her safety, the need for alternative positioning and comfort, and the presence of stable vital signs prior to the procedure. In addition, you have the responsibility to determine the patient's response to the enema. If delegating this task to a UCP:

- Inform and assist the UCP in the proper way to position patients who have mobility restrictions, such as patients with arthritis or severe fatigue.
- Instruct the UCP how to position patients who have therapeutic equipment present, such as drains, intravenous catheters, or traction.
- Instruct the UCP about the specific signs and symptoms that will appear in patients not tolerating the procedure and about when the procedure must be stopped. For example, these signs and symptoms may include abdominal pain more than a pressure sensation, abdominal cramping, abdominal distension, or rectal bleeding.

Equipment

- Clean gloves
- Water-soluble lubricant
- Waterproof, absorbent pads
- Bath blanket
- Toilet tissue
- Bedpan, bedside commode, or access
- Washbasin, washcloths, towel
- Intravenous (IV) pole
- Enema bag administration
- Enema container
- Tubing and clamp (if not already attached to the enema container)
- Appropriate size rectal tube: 22 to 30 Fr
- Correct volume of warmed solution: 750 to 1000 mL
- Prepackaged enema
- Prepackaged enema container with rectal tip

Procedure

STEPS

1. Assess the status of the patient: last bowel movement, normal bowel patterns, presence of hemorrhoids, mobility, external sphincter control, and abdominal pain.
2. Assess the patient for presence of increased intracranial pressure, glaucoma, or recent rectal or prostate surgery.
3. Check the patient's medical record to clarify the rationale for the enema.
4. Review the physician's order for the enema.
5. Determine the patient's level of understanding of the purpose of the enema.
6. Perform hand hygiene. Collect appropriate equipment.
7. Correctly identify the patient and explain the procedure.
8. Assemble the enema bag with the appropriate solution and rectal tube.
9. Perform hand hygiene and apply gloves.
10. Provide privacy by closing the curtains around the bed or by closing the door.
11. Raise the bed to an appropriate working height; raise the side rail on the patient's left side.
12. Assist the patient into a position lying on the left side with right knee flexed (i.e., Sims' position).

RATIONALE

- Your assessment determines the factors indicating a need for enema and influences the type of enema used.
- These conditions contraindicate the use of an enema.
- You need to determine the purpose of the enema administration, either as a preparation for a special procedure or for relief of constipation.
- An order by a physician is required. The order determines the number and type of enemas to be given.
- The patient's current level of understanding allows you to plan for appropriate teaching measures.
- Proper hand hygiene reduces the transmission of microorganisms.
- Explaining the procedure promotes patient cooperation and reduces anxiety.
- Proper hand hygiene reduces the transmission of microorganisms.
- Privacy reduces the embarrassment for the patient.
- Raising the bed and use of the side rail promote good body mechanics and patient safety.
- The Sims' position allows the enema solution to flow downward by gravity along the natural curve of the sigmoid colon and rectum, thus improving retention of the solution.

Critical Decision Point: Patients who have poor sphincter control will have difficulty retaining the enema solution. If the patient is suspected of having poor sphincter control, position the patient on a bedpan.

13. Place a waterproof pad under the hips and buttocks.
14. Cover the patient with a bath blanket, exposing only the rectal area, with the anus clearly visible.
15. Place the bedpan or commode in an easily accessible position. If the patient will be expelling contents in toilet, ensure the toilet is available. (If the patient will be walking to the bathroom to expel the enema, place the patient's slippers and bathrobe in an easily accessible position.)
16. Administer the enema:
 - A. Enema bag
 - A waterproof pad prevents soiling of the bed linen.
 - The bath blanket provides warmth, reduces exposure of body parts, and allows the patient to feel more relaxed and comfortable.
 - A bedpan or commode should be nearby in case the patient is unable to retain the enema solution.

► SKILL 44-1 Administering a Cleansing Enema—cont'd

video

- (1) Add warmed solution to the enema bag: warm the tap water as it flows from faucet, place the saline container in a basin of hot water before adding saline to the enema bag, check the temperature of the solution with a bath thermometer or by pouring a small amount of solution over your inner wrist.
- (2) Raise the container, release the clamp, and allow the solution to flow long enough to fill the tubing.
- (3) Reclamp the tubing.
- (4) Lubricate 6 to 8 cm of the tip of the rectal tube with lubricating jelly.
- (5) Gently separate the buttocks and locate the anus. Instruct the patient to relax by breathing out slowly through the mouth.
- (6) Insert the tip of the rectal tube slowly by pointing the tip in the direction of the patient's umbilicus (see Step 16A[6] illustration) for about 7 to 10 cm.

Step 16A(6) Insertion of a rectal tube into the rectum.

Critical Decision Point: If the tube does not pass easily, do not force it. Consider allowing a small amount of fluid to infuse and then try reinserting the tube slowly.

- (7) Hold the tubing in the rectum constantly until the end of the fluid instillation.
 - (8) Open the regulating clamp and allow the solution to enter slowly with the enema container at the patient's hip level.
 - (9) Raise the height of the enema container slowly to the appropriate level above the anus: 30 to 45 cm for a high enema, 30 cm for a regular enema, 7.5 cm for a low enema (see Step 16A[6] illustration). Instillation time varies depending on the volume of solution administered.
 - (10) Lower the container or clamp tubing if the patient complains of cramping or if fluid escapes around the rectal tube.
 - (11) Clamp the tubing after all solution is instilled.
- B. Prepackaged disposable container**
- (1) Remove the plastic cap from the rectal tip. The tip is already lubricated, but more jelly can be applied as needed.
 - (2) Gently separate the buttocks and locate the rectum. Instruct the patient to relax by breathing out slowly through mouth.
 - (3) Insert the tip of the bottle gently into the rectum about 7 to 10 cm.
 - (4) Squeeze the bottle until all the solution has entered the rectum and colon. Instruct the patient to retain the solution until the urge to defecate occurs, usually within two to five minutes.

- Hot water can burn intestinal mucosa. Cold water can cause abdominal cramping and is difficult to retain.
- Raising the container removes air from the tubing.
- Reclamping prevents further loss of the solution.
- The lubricating jelly allows smooth insertion of the rectal tube without risk of irritation or trauma to the mucosa.
- Exhaling promotes relaxation of the external anal sphincter.
- Careful insertion prevents trauma to the rectal mucosa from an accidental lodging of the tube against the rectal wall. Insertion beyond the proper limit can cause bowel perforation.

- Bowel contractions can cause expulsion of the rectal tube.
- Rapid instillation can stimulate evacuation of the rectal tube.
- Raising the height slowly allows for continuous, slow instillation of the solution. Raising the container too high causes rapid instillation and possible painful distension of the colon.
- Temporary cessation of instillation prevents cramping, but may prevent the patient from retaining all the fluid, thus altering the effectiveness of the enema.
- Clamping prevents entrance of air into the rectum.
- Lubrication provides for smooth insertion of rectal tube while avoiding rectal irritation or trauma.
- Breathing out promotes relaxation of the external rectal sphincter.
- Gentle insertion prevents trauma to the rectal mucosa.
- Hypertonic solutions require only small volumes to stimulate defecation.

Continued

► SKILL 44-1 Administering a Cleansing Enema—cont'd

video

17. Place layers of toilet tissue around the tube at the anus and gently withdraw the rectal tube.
 18. Explain to the patient that the feeling of distension is normal. Ask the patient to retain the solution for as long as possible while lying quietly in bed.
 19. Discard the enema container and tubing in the proper receptacle, or rinse thoroughly with warm soap and water if the container is to be reused.
 20. Assist the patient to the bathroom or help to position the patient on a bedpan.
 21. Observe the character of the feces and solution (caution the patient against flushing the toilet until you can inspect the feces).
- The use of toilet paper provides the patient with comfort and cleanliness.
 - The enema solution distends the bowel. The length of retention varies depending on the type of enema and the patient's ability to contract the rectal sphincter. Longer retention promotes more effective stimulation of peristalsis and defecation.
 - Proper handling of the used enema container and tubing reduces the transmission and growth of microorganisms.
 - The normal squatting position promotes defecation.
 - The character of the expelled feces determines the efficacy of the enema.

Critical Decision Point: When enemas are ordered “until clear,” observe the contents of the solution passed. Return is “clear” when no solid fecal material exists, but solution may be coloured.

22. Assist patient as needed to wash the anal area with warm soap and water (if providing perineal care, use gloves).
 23. Remove and discard gloves and perform hand hygiene.
 24. Inspect the colour, consistency, and amount of stool and fluid passed.
 25. Assess the condition of the abdomen; cramping, rigidity, or distension can indicate a serious problem.
- Fecal contents can irritate the skin. Proper hygiene promotes the patient's comfort.
 - Proper hand hygiene reduces the transmission of microorganisms.
 - The colour, consistency, and amount of stool determines whether the stool is evacuated or fluid is retained. Note any abnormalities, such as the presence of blood or mucus.
 - The condition of the abdomen determines whether distension is relieved. Excess volume can distend or perforate the bowel.

Unexpected Outcomes

Rigidity and distension of the abdomen

Abdominal pain or cramping

Bleeding

Related Interventions

- Stop the enema administration if fluid is still being instilled.
- Notify the physician and obtain vital signs.
- Slow the rate of instillation.
- Stop the enema administration.
- Notify the physician and obtain vital signs.

Recording and Reporting

- Record the type and volume of the enema given and the characteristics of the results.
- Report to the physician if the patient failed to defecate.

Home Care Considerations

- For patients who require enemas for bowel preparation at home, instruct the patient's family not to exceed the recommended fluid volume levels or the recommended number of enemas. Emphasize to the family members the need for slow administration of warmed fluid.

The Salem sump tube is preferable for stomach decompression. This tube has two lumina: one for removal of gastric contents (Figure 44-12) and one to provide an air vent. A blue “pigtail” is the air vent that connects with the second lumen. When the sump tube's main lumen is connected to suction, the air vent permits free, continuous drainage of secretions. The air vent should never be clamped off, connected to suction, or used for irrigation.

Bowel Diversions

Certain diseases cause conditions that prevent the normal passage of feces through the rectum. The treatment for these disorders may result in the need for a **stoma**, which is a temporary or permanent artificial opening in the abdominal wall. The opening may be either an **ileostomy**, a surgical opening in the ileum, or a **colostomy**, a surgical opening in the colon. The ends of the intestine are brought through the abdominal wall to create the stoma (RNAO, 2009).

The standard bowel diversion creates a stoma, or the patient can undergo reconstructive surgery that uses the

native sphincter for bowel continence. The reconstructive surgery includes either a continent stoma procedure, which is now rarely done, or the ileoanal pouch anastomosis, which is described later (Canadian Association for Enterostomal Therapy [CAET], 2008b).

Ostomies. The location of the ostomy determines the consistency of the stool. An ileostomy bypasses the entire large intestine. As a result, stools are frequent and liquid. The same is true for a colostomy of the ascending colon (Figure 44-13). A colostomy of the transverse colon, in general, results in a more solid, formed stool (see Figure 44-13). The descending colostomy and sigmoid colostomy emit a near-normal stool (see Figure 44-13). The location of a colostomy is determined by the patient's medical problem and general condition. Colostomies have three types of construction: loop colostomy, end colostomy, and double-barrel colostomy.

Loop Colostomy. A loop colostomy is usually performed in a medical emergency when closure of the colostomy is anticipated. Loop colostomies are usually temporary large stomas constructed in the transverse colon. The surgeon pulls a loop

► BOX 44-10 Procedural Guideline

Digital Removal of Stool

Delegation Considerations:

The digital removal of stool procedure should not be delegated to unregulated care providers (UCPs).

Equipment:

- Bath blanket
- Waterproof pad
- Clean gloves
- Lubricant
- Towel
- Washcloth
- Soap and water
- Bedpan

Procedure:

1. Check the patient record for a physician's order to manual disimpaction.
2. Explain the procedure to the patient.
3. Perform hand hygiene. Take baseline vital signs prior to the procedure. Help the patient to lie on the left side with knees flexed and back toward you.
4. Drape the trunk and lower extremities with a bath blanket and place a waterproof pad under the buttocks. Keep a bedpan next to the patient.
5. Apply disposable gloves and lubricate the index finger of your dominant hand with lubricating jelly.
6. Gently insert the gloved index finger into the rectum and advance the finger slowly along the rectal wall toward the umbilicus.
7. Gently loosen the fecal mass by massaging around it. Work the finger into the hardened mass.
8. Work the feces downward toward the end of the rectum. Remove small pieces at a time and discard into the bedpan.
9. Reassess the patient's vital signs and look for signs of fatigue. Stop the procedure if the heart rate drops significantly or if the heart rhythm changes. Monitor for one hour postprocedure.
10. Continue to remove feces and allow the patient to rest at intervals.
11. After completion, wash and dry the buttocks and anal area.
12. Remove the bedpan and dispose of the feces. Remove gloves by turning them inside out, and then discard.
13. Assist the patient to the toilet or position the patient on a clean bedpan if the urge to defecate develops.
14. Perform hand hygiene. Record results of the removal of the impaction by describing the fecal characteristics.
15. Follow the procedure with enemas or cathartics as ordered by physician.
16. Reassess the patient's vital signs and level of comfort.

of bowel onto the abdomen. The loop ostomy has two openings through the one stoma (see Figure 44-13). The proximal end drains stool, whereas the distal portion drains mucus (Monahan et al., 2007).

End Colostomy. The end colostomy consists of one stoma formed from one end of the bowel with the distal portion of the GI tract either removed or sewn closed (known as Hartmann's pouch) and left in the abdominal cavity. For many patients, end colostomies are a result of surgical treatment for colorectal cancer. In such cases, the rectum might also be

► TABLE 44-6 Purposes of Nasogastric Intubation

Purpose	Description	Type of Tube
Decompression	Removal of secretions and gaseous substances from the gastrointestinal tract to prevent or relieve abdominal distension	Salem sump, Levin, Miller-Abbott
Feeding (i.e., gavage; see Chapter 42)	Instillation of liquid nutritional supplements or feedings into the stomach for patients unable to swallow fluid	Duo, Dobhoff, Levin
Compression	Internal application of pressure by means of an inflated balloon to prevent internal esophageal or gastrointestinal hemorrhage	Sengstaken-Blakemore
Lavage	Irrigation of the stomach in cases of active bleeding, poisoning, or gastric dilation	Levin, Ewald, Salem sump

Source: Courtesy Dr. Norma Metheny, St Louis University, School of Nursing, St Louis, MO.

removed. Patients with diverticulitis who are treated surgically often have a temporary end colostomy with a Hartmann's pouch (Figure 44-14).

Double-Barrel Colostomy. In a double-barrel colostomy (as opposed to the loop colostomy), the bowel is surgically severed and the two ends are brought out onto the abdomen (see Figure 44-13). The double-barrel colostomy consists of two distinct stomas: the proximal functioning stoma and the distal nonfunctioning stoma.

Kock Continent Ileostomy. The Kock continent ileostomy is created using the patient's small intestine to create a pouch. This procedure is occasionally used in the treatment of ulcerative colitis. The pouch has a continent stoma, which is a nipple-type valve that is drained with an external catheter. The patient places the external catheter intermittently in the stoma and empties the pouch several times a day. The stoma is covered with a protective dressing or a stoma cap (RNAO, 2009).

Published with permission.

however, a well-placed stoma should not interfere with the patient's activities and can be concealed by clothing (Banks & Razor, 2003). Although clothing may conceal the ostomy, the patient feels different. Many patients have difficulty maintaining or initiating normal sexual relations. An important factor in the patient's reactions is the character of the fecal secretions and the ability to control them. The patient's self-esteem can be impaired by foul odours, spillage, or leakage of liquid stools and the inability to regulate bowel movements.

Care of Ostomies. Patients with temporary or permanent bowel diversions have unique bowel elimination needs. Individuals with an ostomy wear a pouch or appliance to collect the **effluent** (the stool discharged from an ostomy) from the stomas (RNAO, 2009). These patients must use meticulous skin care to prevent liquid stool from irritating the skin around the stoma (Figure 44-15).

Irrigating a Colostomy. Although this practice is not as common as it once was, some patients may be instructed to irrigate their left-sided colostomies in order to regulate colon emptying. Other patients do not want to spend the additional 60 to 90 minutes in the bathroom every day, and they empty their pouch only as necessary (CAET, 2008a).

Specific equipment for irrigating a colostomy should be used. An enema set should never be used to irrigate a colostomy. A special cone-tipped irrigator (Figure 44-16) is used. This device prevents both bowel penetration and backflow of the irrigating solution. Patients usually sit on the toilet and place an irrigating sleeve over the stoma. The end of this sleeve extends into the bowl of the toilet. The physician orders the amount and type of solution. For adults, the amount ranges from 500 to 700 mL of tap water. The solution is instilled slowly through the lubricated cone tip. Irrigation should take 5 to 10 minutes. The patient then removes the cone tip and waits 30

Psychological Considerations. A stoma can cause serious body-image changes, particularly when it is permanent. A classic study reported by Walsh et al. (1995) measured the perception of body image in patients who had a stoma. Patients who had a longstanding history of chronic bowel disease, such as Crohn's disease or ulcerative colitis, reported an improved quality of life but a lower body image. Conversely, patients who needed an ostomy because of cancer reported a higher body image but a reduced quality of life. Patients often perceive a stoma as invasive and disfiguring;

Appendix E: Sample Ostomy Teaching Record

OSTOMY TEACHING RECORD

Client: _____

Address: _____

Before Surgery: Teaching Completed	Date & Initial
Date of surgery	
Type of surgery/ostomy	
Reason for surgery	
E.T. Nurse visit	
Stoma site selection and marking	
Stoma location and appearance	
Given teaching booklets about surgery	
Given samples of pouching system	
Purpose of pouch and skin barrier	
Knowledge of others with an ostomy	
Viewed ostomy video	

After Surgery: While in Hospital Teaching Completed	Date & Initial
Stoma (size, swelling, shrinkage and appearance)	
Type of drainage while in hospital	
Observe/assist with pouch emptying	
Independent with pouch emptying	
Observe/assist with release of gas from pouch	
Independent with release of gas from pouch	
Observe/assist with pouch and skin barrier change	
Discuss odour control options	
Signs of pouch leakage (prevention and treatment)	
Viewed ostomy video and given teaching booklet (if not done pre-op)	
Who to call if problems occur after discharge from hospital	

After Surgery: Discharged Home Teaching Completed	Date & Initial
Type of drainage at home	
Stoma (size, swelling, shrinkage and appearance)	
Independent with pouch emptying	
Observe/assist with pouch and skin barrier change	
Independent with pouch and skin barrier change	
Signs of pouch leakage (prevention and treatment)	
Skin breakdown (prevention and treatment)	
Application instructions	
Supply list/where to buy	
Care of supplies/emergency kit	
Discuss odour control options	
Nutrition/dietary instructions	
Bathing	
Activity/travel	
Clothing modifications	
Sexual function concerns	
Financial Assistance (A.D.P., Private Insurance, Social Assistance, Disability)	
United Ostomy Association of Canada Support Group	
Ostomy visitor	
Discharge instructions	

Colostomy: Teaching Completed	Date & Initial
Care of perineal wound (if present)	
Mucous drainage per rectum (if rectum left in place)	
Care of a mucous fistula (if present)	
Colostomy irrigation information	
Trial of a colostomy irrigation (optional)	
Constipation/diarrhea/gas	

Ileostomy: Teaching Completed	Date & Initial
Care of perineal wound (if present)	
Mucous drainage per rectum (if rectum left in place)	
Sodium loss and replacement	
Potassium loss and replacement	
Obstruction and management	
Fluid imbalance and treatment	
Medication

Figure 44-16 Ostomy irrigation cone inserted into the stoma.

to 45 minutes for the solution and feces to drain out of the irrigation sleeve. Once the drainage stops, the patient applies a stoma cap or a pouch. If a patient chooses to irrigate the colostomy, the timing of the irrigation can be individualized to the patient's lifestyle.

Pouching Ostomies. Ostomies require a pouch to collect fecal material. An effective pouching system protects the skin, contains fecal material, remains odour-free, and is comfortable

and inconspicuous. A person wearing a pouch should feel secure in participating in any activity.

Many pouching systems are available. To ensure that a pouch fits well and meets the patient's needs, consider the location of the ostomy; the type and size of the stoma; the amount and consistency of the effluent; the size and contour of the abdomen; the condition of the skin around the stoma; skin sensitivities or allergies; the physical activities of the patient; cognitive abilities for learning; the patient's personal preference, age, and dexterity; and the cost of the equipment. An **enterostomal therapist (ET)** is a nurse trained to care for wound and ostomy management. The staff nurse collaborates with the ET to ensure the correct pouching system is used. For example, a referral to an ET nurse would be appropriate to plan the care of a patient who has a high-output ostomy that requires a pouch modification.

A pouching system consists of a pouch and a skin barrier (Figure 44-17). Pouches come in one- and two-piece systems that are disposable or reusable. Some pouches have the opening precut by the manufacturer; others require the stoma opening to be custom cut to the patient's specific stoma size.

Skin barriers include wafers, pastes, powders, and liquid film that are applied to the skin around the stoma. Wafer skin barriers, which are permanently attached to the ostomy pouch,

Figure 44-17 Common ostomy pouch products, closures, and patches. **A**, Drainable pouches and pouch closures. **B**, Non-drainable pouches. **C**, Patches for regulated colostomies. **Source:** Monahan, F. D., Neighbors, M., Sands, J. K., Marek, J. F., & Green, C. J. (2007). *Phipps' medical-surgical nursing: Health and illness perspectives* (8th ed., p. 1264, Fig. 43-11). St Louis, MO: Mosby Elsevier.

are called one-piece pouch systems. In a two-piece system, the pouch can be detached from the skin barrier for emptying or changing. This system allows the skin barrier to remain around the patient's stoma for several days, thus minimizing the chance of skin damage from too-frequent removal of the skin barrier from the peristomal skin (Figure 44-18). When using a two-piece pouching system, the skin barrier and pouch must be the same corresponding size and from the same manufacturer. The pouch from one manufacturer will not fit correctly on the skin barrier from another manufacturer. Ensure the patient understands to use an ostomy pouch made for collecting fecal matter (i.e., a pouch specifically for a colostomy or ileostomy) and not a pouch for collecting urine.

Instruct patients to measure the stoma size carefully when selecting and cutting out the opening on the wafer skin barrier. A good skin barrier protects the skin, prevents irritation from repeated removal of the pouch, and is comfortable for the patient to wear. Skill 44-2 describes the steps for applying one type of pouch system.

Nutritional Considerations for Patients with Ostomies. Nutritional therapy is important for patients with ostomies. During the first weeks after surgery, many physicians recommend low-fibre diets, particularly for ileostomy patients,

Figure 44-18 **A**, Mechanical injury to the peristomal skin. **B**, Candidiasis damage to the peristomal skin. **Source:** Permission to use these copyrighted photos has been granted by the owner, Hollister Incorporated.

because the small bowel requires time to adapt to the diversion. Low-fibre foods include bread, noodles, rice, cream cheese, eggs (not fried), strained fruit juices, lean meats, fish, and poultry. As ostomies heal, patients can eat almost any food. High-fibre foods, such as fresh fruits and vegetables, help to ensure a more solid stool, which is needed to achieve success at irrigation. Blockage must be avoided. The stoma's surgical construction can affect the likelihood of blockage.

Patients with an ileostomy should eat slowly and chew their food completely. Drinking 10 to 12 glasses of water daily also helps to prevent blockage. High-fibre foods that may cause problems include stringy meats; mushrooms; popcorn; some fruits, such as cherries; and some seafood, such as shrimp and crab. Ostomy patients may benefit from avoiding foods that cause gas and odour, such as broccoli, cauliflower, dried beans, and Brussels sprouts.

❖Evaluation

Patient Care

The effectiveness of care depends on success in meeting the goals and expected outcomes of care. Optimally, the patient will be able to have regular, pain-free defecation of soft, formed stools. The patient is the only person who is able to determine whether the bowel elimination problems have been relieved and which therapies were the most effective (Figure 44-19). The patient will also be able to demonstrate information learned regarding establishment of a normal bowel elimination pattern. The patient will be able to demonstrate any skills learned, such as ostomy protocols and skin protection. The patient will be able to accomplish normal defecation by manipulating components of daily living, such as diet, fluid intake, and exercise. The patient will have minimal reliance on artificial means of defecation, such as enemas and laxative use.

Patient Expectations

If you have been successful in establishing a therapeutic relationship with the patient, the patient will feel more comfortable in discussing the intimate details often associated with bowel elimination. The patient will also not be as fearful of

► SKILL 44-2 Pouching an Ostomy

Delegation Considerations

The skill of pouching a newly established ostomy should not be delegated to unregulated care providers (UCPs). Pouching of a well-established ostomy can be delegated to a UCP. You must do the following:

- Assist the caregiver in selecting the appropriate pouch and skin barrier.
- Inform the caregiver of the signs of stomal and peristomal skin changes that should be reported to a nurse.
- Ask the caregiver to monitor and report the characteristics and volume of the ostomy output and report changes in volume or consistency to you for further assessment.

Equipment

- Clear drainable colostomy (or ileostomy) pouch in the correct size for a two-piece system or custom cut to fit a one-piece system with an attached skin barrier
- Pouch closure device, such as a clamp or clip if needed
- Clean gloves
- Gauze pads and washcloths
- Towel or disposable waterproof barrier
- Basin with warm tap water
- Scissors and pen
- Adhesive remover (optional)

Procedure

STEPS

1. Perform hand hygiene.
2. Apply gloves. Observe the skin barrier and pouch for leakage and the length of time in place. Depending on the type of pouching system used (e.g., an opaque pouch), you may need to remove the pouch to fully observe the stoma. Clear pouches permit the viewing of the stoma without their removal.

RATIONALE

- Leakage may indicate the need for a different type of pouch or sealant.

Critical Decision Point: Intact skin barriers with no evidence of leakage do not need to be changed daily and can remain in place for three to five days (depending on manufacturer's guidelines).

3. Observe the stoma for colour, swelling, trauma, and healing; the stoma should be moist and reddish-pink. Assess the type of stoma. Stomas can be flush with the skin or can be a bud-like protrusion on the abdomen.
4. Measure the stoma at each pouching change. Follow the pouch manufacturer's directions and measuring guide to determine which pouch to use on the basis of the patient's stoma size. The opening around the appliance should be no greater than 2 mm larger than the stoma (Perry & Potter, 2010).
5. Observe the abdominal incision (if present).
6. Observe the effluent from the stoma and record the intake and output. Empty the pouch if it is more than one-third to one-half full. Ask the patient about skin tenderness. Remove gloves and perform hand hygiene.
7. Assess the abdomen for the best type of pouching system to use. Consider the following:
 - A. Contour and peristomal plane
 - B. Presence of scars, incisions
 - C. Location and type of stoma
8. Assess the patient's self-care ability to determine the best type of pouching system to use.
9. After removing the skin barrier and pouch, assess the skin around the stoma, noting scars, folds, skin breakdown, and the peristomal suture line, if present. Keep the pouch loosely attached to the stoma to collect any drainage while the system is being changed.

- Stoma characteristics are one factor to consider when selecting an appropriate pouching system.
- The size of the stoma determines the correct size of equipment, which prevents trauma to the stoma. Too large an opening can permit fecal drainage to ooze from under the appliance, causing skin irritation. Too small an opening can cause the appliance to cut into the stoma (Perry & Potter, 2010).
- The relationship of the abdominal incision to the stoma determines proper placement of the pouch.
- Effluent from the stoma is caustic. If effluent comes in contact with the sensitive peristomal skin, the risk of skin breakdown increases. Pouches must be emptied because the weight of the pouch may disrupt the seal of adhesive on the skin (Perry & Potter, 2010).
- The characteristics of the abdomen determine the pouching system selection and the need for additional equipment. For a stoma to have an adequate seal with an ostomy appliance, the stoma must be placed within the abdominal rectus muscle, away from abdominal creases and folds, away from the bony understructures, and surrounded by at least 5 cm of smooth surface on all sides (Perry & Potter, 2010).
- Patients who have difficulty using their hands or who have limited vision may find a one-piece system or a precut pouch and skin barrier more desirable to use; others prefer being able to keep the skin barrier in place for several days, changing just the pouch, and therefore prefer the two-piece system.
- Assessing the skin around the stoma determines the need for barrier paste to increase adherence of the pouch to the skin or to fill in irregularities.

Critical Decision Point: If the skin around the stoma is discoloured, weeping, itchy, or sore, refer the patient to an ostomy specialist (Perry & Potter, 2010).

► SKILL 44-2 Pouching an Ostomy—cont'd

10. Determine the patient's emotional response, knowledge, and understanding of an ostomy and its care.
 11. Explain the procedure to the patient; encourage the patient's interaction and questions.
 12. Perform hand hygiene. Assemble the equipment and close the room curtains or door.
 13. Position the patient either standing or in a semi-reclining position and draped. If seated, position the patient either on or in front of the toilet.
 14. Perform hand hygiene and apply disposable gloves.
 15. Place the towel or disposable waterproof barrier under the patient.
 16. Completely remove the used pouch and skin barrier by gently pushing the skin away from the barrier. An adhesive remover may be used to facilitate removal of the skin barrier.
 17. Clean the peristomal skin gently with warm tap water using gauze pads or a clean washcloth; do not scrub the skin; dry completely by patting the skin with gauze or towel.
 18. Measure the stoma for the correct size of pouching system needed, using the manufacturer's measuring guide (see Step 18 illustration).
 19. Select the appropriate pouch for the patient on the basis of your patient assessment. For a custom cut-to-fit pouch, use an ostomy guide to cut an opening on the pouch 2 mm larger than the stoma before removing the backing (Perry & Potter, 2010). Prepare the pouch by removing the backing from the barrier and adhesive (see Step 19 illustration). For an ileostomy, apply a thin circle of barrier paste around the opening in the pouch; allow to dry.
- Understanding the patient's perspective assists in determining both the extent to which the patient is able to participate in care and the patient's need for teaching and the clarification of information.
 - Explaining the procedure reduces the patient's anxiety and promotes the patient's participation.
 - Proper hand hygiene reduces the transmission of infection. Organizing the equipment optimizes the use of time and conserves the patient's and nurse's energy. Privacy reduces the embarrassment for the patient.
 - When the patient is semi-reclined, fewer wrinkles ease the application of the pouching system; draping maintains the patient's dignity.
 - Proper hand hygiene reduces the transmission of microorganisms.
 - The towel or waterproof barrier protects the bed linen.
 - Working gently reduces trauma; jerking irritates the skin and can cause tears.
 - Avoid the use of soap because it leaves a residue on the skin that interferes with pouch adhesion to the skin. Skin must be as dry as the skin barrier; the pouch does not adhere to wet skin. If blood appears on the gauze pad, do not be alarmed; the stoma, if rubbed, may ooze some blood from the cleaning process. The stoma's surface is a highly vascular mucous membrane. Bleeding into the pouch is abnormal.
 - Measuring the stoma ensures accuracy in determining the correct pouch size needed. The stoma shrinks and does not reach its usual size for six to eight weeks.
 - The barrier paste facilitates the seal and protects the skin. The size of the pouch opening keeps drainage off the skin and reduces the risk of damage to the stoma during peristalsis or physical activity. The pouch and skin barrier are changed whenever leaking occurs. They can also be changed before or after a tub bath or shower. The stool is alkaline, which is an irritant on the skin; fecal bacteria can colonize on the skin and increase the risk of infection. Change the pouch and skin barrier when the patient is comfortable; before a meal is better because this timing avoids increased peristalsis and the chance of evacuation during the pouch change.

Step 18 Measuring a stoma.

Step 19 Preparing an ostomy pouch.

► SKILL 44-2 Pouching an Ostomy—cont'd

Critical Decision Point: If patient has a large volume of liquid stool from an ileostomy, consider using a high-output pouch that will contain the volume of effluent and reduce the frequency of pouch emptying.

20. Apply the skin barrier and pouch. If creases occur next to the stoma, use a barrier paste to fill in; let dry one to two minutes.

Critical Decision Point: If the patient has a surgical incision near the stoma, the skin barrier may need to be trimmed to fit.

A. For a one-piece pouching system:

- (1) Use skin sealant wipes on the skin directly under the adhesive skin barrier or pouch; allow to dry. Press the adhesive backing of the pouch or skin barrier smoothly against the skin, starting from the bottom and working up and around the sides.
- (2) Hold the pouch by the barrier, centre it over the stoma, and press down gently on the barrier; the bottom of the pouch should point toward the patient's knees (see Step 20A[2] illustration).
- (3) Maintain gentle finger pressure around the barrier for one to two minutes.

B. For a two-piece pouching system:

- (1) Apply the flange (the barrier with adhesive) as in steps above for a one-piece system (see Step 20B[1] illustration). Then snap on the pouch and maintain finger pressure.

- The flange creates a wrinkle-free, secure seal and decreases irritation from the adhesive on skin.

Step 20A(2) Applying a one-piece pouch. **Source:** Courtesy ConvaTec, Princeton, NJ.

C. For both pouching systems, gently tug on the pouch in a downward direction.

21. Apply a nonallergenic paper tape around the pectin skin barrier in a "picture frame" method. Half of the tape should be on the skin barrier and half on the patient's skin. Some patients prefer a belt attached to the pouch for extra security in place of the tape.

Critical Decision Point: If the patient chooses to wear a belt, ensure it is not fastened too tightly by placing two fingers between the belt and the patient's skin.

22. Fold the bottom of drainable open-ended pouches up once and close using a closure device such as a clamp (or follow the manufacturer's instructions for closure).
23. Properly dispose of the old pouch and the soiled equipment.
24. Remove gloves and perform hand hygiene.
25. Change a one- or two-piece pouch every three to seven days unless it is leaking; a pouch can remain in place for tub bath or shower; after a bath or shower, pat the adhesive dry.

- Proper closure maintains a secure seal to prevent leaking.

- Proper hand hygiene reduces the transmission of microorganisms.
- Avoid unnecessary trauma to the skin from too frequent changes. Drying the adhesive ensures the adhesion of the pouch.

Step 20B(1) Application of a barrier-paste flange. **Source:** Courtesy ConvaTec, Princeton, NJ.

- Tugging on the pouch determines whether the pouch is securely attached.
- "Picture framing" the pectin skin barrier adds to the security of keeping the pouch system attached securely.

► SKILL 44-2 Pouching an Ostomy—cont'd

26. Ask whether the patient feels discomfort around the stoma.
 27. While the pouch is removed and the skin is being cleaned, note the appearance of the stoma around the skin and the existing incision (if present). Re-inspect the condition of the skin barrier and adhesive.
 28. Observe the patient's nonverbal behaviours as the pouch is applied. Ask whether the patient has any questions about the pouching.
- The patient's perception of discomfort determines the presence of skin irritation.
 - Assessing the skin and existing incision determines the condition of the tissues and the progress of healing. The condition of the skin barrier and adhesive can detect the presence of leaks.
 - Nonverbal behaviours indicate the patient's emotional response to the stoma and the readiness for learning. The patient's questions determine the level of understanding of the procedure.

Unexpected Outcomes

Damage of the peristomal skin

Necrosis of stoma (purple or black discolouration, dryness, failure to bleed, or sloughing of tissue)

Related Interventions

- Assess for the following conditions and report their occurrence to the physician for treatment:
 - Mechanical damage (see Figure 44-18, A) due to inappropriate skin care or incorrect tape removal)
 - Chemical damage due to the effluent coming into contact with the peristomal skin or a skin reaction to the adhesive
 - Damage due to a fungus (e.g., candidiasis; see Figure 44-18, B), usually caused by excessive skin moisture
- Assess the circulation to the stoma.
- Observe for excessive edema or tension on the bowel suture line (if present).
- Immediately report this finding to the physician.

Recording and Reporting

- Chart the type of pouch and skin barrier applied.
- Record the amount, appearance, and texture of the stool; the condition of the peristomal skin; and the condition of any sutures.
- Report any of the following to the charge nurse or the physician, or both:
 - Any abnormal appearance of the stoma, the suture line, the peristomal skin, the character of output, or the absence of bowel sounds.
 - No flatus in 24 to 36 hours and no stool by the third day.
 - Document abdominal distension, excessive tenderness, and the nature of bowel sounds.
- Record the patient's level of participation and need for instruction.

Home Care Considerations

- Evaluate the patient's home toileting facilities. Note the presence of adequate toileting facilities.
- Caution the patient that most ostomy pouches and barriers cannot be flushed down the toilet; they clog the plumbing system. Dispose of used ostomy pouch according to agency policy and local sanitation regulations.

embarrassment as you assist the patient with his or her bowel elimination needs. The patient will relate a feeling of comfort and freedom from pain as bowel elimination needs are met within the limits of the patient's condition and treatment.

❖ KEY CONCEPTS

- The mechanical breakdown of food elements, gastrointestinal motility, and selective absorption and secretion of substances by the large intestine influence the character of feces.
- Food high in fibre content and an increased fluid intake keep feces soft.
- Ongoing use of cathartics, laxatives, and enemas affects and delays the reflexes of normal defecation.
- Vagal stimulation, which slows the heart rate, may occur during straining while defecating, receiving enemas, and during digital removal of an impacted stool.
- The greatest danger from diarrhea is developing an imbalance of fluids and electrolytes.
- The location of an ostomy influences the consistency of the stool.
- Assessment of bowel elimination patterns should focus on bowel habits, factors that normally influence defecation, recent changes in bowel elimination, and a physical examination.
- Indirect and direct visualization of the lower gastrointestinal tract requires cleansing of the bowel before the procedure.
- When selecting a diet to promote normal bowel elimination, consider the frequency of defecation, the fecal characteristics, and the effect of foods on the gastrointestinal function.
- Proper positioning on a bedpan allows the patient to assume a position similar to squatting without experiencing muscle strain.
- Nasogastric intubation decompresses the gastric contents by removing secretions and gaseous products from the gastrointestinal tract.
- The purposes of gastric decompression are to keep the gastrointestinal tract free of secretions, to reduce nausea and gas, and to decrease the risk of vomiting and aspiration.
- Proper selection and use of an ostomy pouching system are necessary to prevent damage to the skin around the stoma.
- Dangers during digital removal of stool include traumatizing the rectal mucosa and promoting vagal stimulation.
- Skin breakdown can occur after repeated exposure to liquid stool.

Figure 44-19 Critical thinking model for bowel elimination evaluation.

✦ CRITICAL THINKING EXERCISES

1. A 19-year-old man with a history of good health and regular exercise is your patient at the university health service facility where you work. He complains of increasing diarrhea and abdominal cramping; he has no weight loss. He states that on rare occasions he noticed blood on the toilet paper he used. What additional pieces of assessment data do you need?
2. A long-term care facility has invited you to present a talk on preventing bowel incontinence in their residents. What points of information do you include in your presentation?
3. A 22-year-old man is to undergo surgery for Crohn's disease. He will have a new pouching ileostomy. He and his mother need to learn what the ileostomy means for his future bowel elimination needs. What do you tell them?
4. Mrs. Edna Pidpahora is 82 years old and a resident in a long-term care facility. In the Emergency Department, she was just assessed for acute confusion and has been admitted to your ward. In her documentation, you see that she has become more confused and forgetful since she moved into long-term care four months ago. She spends most of her time in bed or sitting in a chair in her room. She is occasionally incontinent of urine and has not had a bowel movement in five days. She is taking the following medications and supplements:

levothyroxine (Synthroid), calcium carbonate, vitamin D, chlorothiazide, risperidone, chloral hydrate. What steps would you take to understand and address her apparent constipation (Neil et al., 2003; Robson et al., 2000; Spina & Scordo, 2002)?

✦ REVIEW QUESTIONS

1. Most nutrients and electrolytes are absorbed in which of the following areas?
 1. Colon
 2. Stomach
 3. Esophagus
 4. Small intestine
2. During the nursing assessment, the patient reveals that he has diarrhea and cramping every time he eats ice cream. He attributes this reaction to the cold nature of the food. These symptoms might be associated with which of the following?
 1. Food allergy
 2. Irritable bowel syndrome
 3. Lactose intolerance
 4. Increased peristalsis
3. You are assessing a 55-year-old patient who is in the clinic for a routine physical examination. Under which of the following scenarios would you instruct the patient to obtain fecal occult blood testing (FOBT)?
 1. The patient has a family history of polyps.
 2. The patient reports rectal bleeding.
 3. A palpable mass is detected on digital examination.
 4. The patient is due for a routine examination for colon cancer.
4. Which of the following agents decreases colonic propulsive contractions while increasing the mixing of contractions?
 1. Antidiarrheal opiate agents
 2. Hypertonics
 3. Cathartics
 4. Laxatives
5. Which of the following situations results in diarrhea that occurs with a fecal impaction?
 1. A clear liquid diet
 2. Irritation of the intestinal mucosa
 3. Seepage of stool around the impaction
 4. Inability of the patient to form a stool
6. A cleaning enema is ordered for a 55-year-old patient before intestinal surgery. What amount of solution should be instilled?
 1. 150 to 200 mL
 2. 200 to 400 mL
 3. 400 to 750 mL
 4. 750 to 1000 mL
7. During the enema, the patient complains of pain. You note rectal bleeding and blood in the return fluid. What action do you take?
 1. Stop the instillation.
 2. Slow the rate of instillation.
 3. Stop the instillation, notify the physician, and obtain vital signs.
 4. Tell the patient to breathe slowly and relax.

8. What is one of the greatest problems in caring for a patient with a nasogastric tube?
 1. Dehydration
 2. Maintaining comfort
 3. Constipation
 4. Nutritional therapy
9. What term is given to the stool discharged from an ostomy?
 1. Effluent
 2. Cathartics
 3. Colonic fluid
 4. Mucosa
10. What term describes a nurse trained to care for ostomy patients?
 1. Enterostomal therapist
 2. Nurse practitioner
 3. Ostomy practitioner
 4. GI therapist

Mobility and Immobility

Written by Donna J. Gill, RN(EC), BScN, MSc, CRN(C)

Based on the original chapter by Ann B. Tritak, BSN, MA, RN, EdD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe the functions of the musculoskeletal (skeleton, skeletal muscles) and nervous systems in the regulation of movement.
- Discuss physiological and pathological influences on body alignment and joint mobility.
- Identify changes in physiological and psychosocial function associated with immobility.
- Assess for correct and impaired body alignment and mobility.
- State correct nursing diagnoses for impaired body alignment and mobility.
- Develop nursing care plans for patients with impaired body alignment and mobility.
- Describe essential techniques when assisting with active and passive range-of-motion (ROM) exercises, assisting a patient to move up in bed, repositioning a patient, assisting a patient to a sitting position, and transferring a patient from a bed to a chair or from a bed to a stretcher.
- Evaluate the nursing care plan for maintaining body alignment and mobility.

Mobility refers to the ability to move easily and independently. To maintain optimal physical mobility, the musculoskeletal and nervous systems of the body must be intact and functioning. Illnesses, surgery, injuries, pain, and aging can temporarily or permanently impair mobility. Nurses need to know the many hazards created by immobility and how to prevent them. Nurses also need to know how to care for patients who are immobile. This care includes positioning the patient who is immobile so that optimal body alignment is attained, and moving and transferring patients when they cannot do so independently. Clinical nursing practice related to mobility requires knowledge of body

mechanics and of the basic structure and function of bones and muscles, which are reviewed in detail in Chapter 35.

Scientific Knowledge Base

Physiology and Principles of Body Mechanics

Body mechanics are the coordinated efforts of the musculoskeletal and nervous systems to maintain balance, posture, and body alignment during lifting, bending, moving, and performing activities of daily living (ADLs). Use of proper body mechanics reduces risk of injury to the musculoskeletal system, facilitates mobility, and allows for efficient use of energy.

By using proper body mechanics, you help ensure the safety and well-being of both you and your patient (see Chapter 35).

Alignment and Balance. The terms **body alignment** and **posture** are analogous and refer to the positioning of the **joints, tendons, ligaments**, and muscles while standing, sitting, and lying. Being in correct *body alignment* means that the individual's centre of gravity is stable. Correct body alignment reduces strain on musculoskeletal structures, minimizes the risk of injuries and falls, aids in maintaining adequate muscle tone, and contributes to balance. Balance is enhanced with a wide base of support and correct body posture and when the body's centre of gravity is kept low and within the base of support (see Chapter 35).

Balance is required for maintaining a static position such as sitting, for performing ADLs, and for moving freely. The ability to balance can be compromised by disease, injury, pain, physical development (e.g., age), life changes (e.g., pregnancy), medications (e.g., in which dizziness or drowsiness is a side effect), and prolonged immobility, which may cause **deconditioning**. Deconditioning is a clinical syndrome that results in reduced functioning of multiple body systems, especially the musculoskeletal system. Nurses must be alert to impaired balance because it is a major threat to physical safety. Impaired balance can also lead to a patient's fear of falls and self-imposed restrictions on activity.

safety alert In Canada, falls are the sixth leading cause of death in older adults. Generalized weakness, impaired balance, and unsteady gait are risk factors for falls among older adults. Injuries from falls contribute to reduced quality of life and increased morbidity, mortality, and health care costs. Most falls in the hospital occur near the patient's bedside while trying to transfer. Nursing actions should include a thorough assessment of patient safety and implementation of strategies to prevent falls such as those outlined in the Registered Nurses' Association of Ontario (RNAO) (2005a) *Best Practice Guideline: The Prevention of Falls and Falls Injuries in the Older Adult*.

Gravity and Friction. *Weight* is the force exerted on a body by gravity. To lift safely, the lifter must overcome the weight of the object to be lifted and know its centre of gravity. In a person, the centre of gravity is usually at 55% to 57% of standing height and is located in the midline. People who are unsteady can fall as their centres of gravity become unbalanced because of the gravitational pull of their weight when it moves outside their base of support.

Friction is a force that occurs in a direction to oppose movement. As you turn, transfer, or move a patient up in bed, friction must be overcome. The larger the surface area of the object

to be moved, the greater the friction. A larger object produces greater resistance to movement. To decrease surface area and reduce friction when a patient is unable to assist in moving up in bed, place the patient's arms across the chest. This position decreases surface area and reduces friction.

Whenever possible, you should use some of the patient's strength when lifting, transferring, or moving the patient. Explain the procedure to the patient and tell the patient when and what body parts to move. The result should be a synchronized movement in which the patient can participate and in which friction is decreased. By involving the patient, you may have the added benefit of increasing the patient's participation in self-care, thus promoting his or her sense of accomplishment.

Lifting a patient, rather than pushing or pulling, can also reduce friction. Lifting has an upward component and decreases the pressure between the patient and the bed or chair. By placing the patient on a friction-reducing device (e.g., slider sheet or transfer board) and then pulling this sheet to move the patient, you can reduce friction, because the patient is raised off the surface and is more easily moved along the bed's surface (see Chapter 35).

Regulation of Movement

Coordinated body movement involves integrated functioning of the skeletal system, skeletal muscle, and nervous system. These three systems cooperate closely in mechanical support of the body. They are discussed as a single functional unit in Chapter 35.

Pathological Influences on Mobility

Many pathological conditions affect mobility, including both congenital and acquired impairments, degenerative and episodic conditions, and diseases affecting virtually every body system. Although a complete description of each is beyond the scope of this chapter, an overview of four categories of pathological influences is presented here: postural abnormalities, impaired muscle development, damage to the central nervous system, and direct trauma to the musculoskeletal system.

Postural Abnormalities. Congenital or acquired postural abnormalities affect the efficiency of the musculoskeletal system, as well as body alignment, balance, and appearance. During assessment, observe body alignment and range of motion (ROM; see Chapter 35). Postural abnormalities can cause pain, impair alignment or mobility, or both. Knowledge about the characteristics, causes, and treatment of common postural abnormalities (Table 45-1) is necessary for lifting, transferring, and positioning a patient. Some postural abnormalities may limit ROM. Nurses intervene to maintain maximum ROM in unaffected joints and then may design interventions to strengthen affected muscles and joints, improve the patient's posture, and adequately use affected and unaffected muscle groups. Referral to or collaboration with a physiotherapist and occupational therapist may enhance your interventions for a patient with a postural abnormality.

Impaired Muscle Development. Injury and disease can lead to numerous alterations in musculoskeletal function. The muscular dystrophies, for example, are a group of familial disorders that cause degeneration of skeletal muscle fibres. The most prevalent of the muscle diseases in childhood, the muscular dystrophies are characterized by progressive, symmetrical weakness and wasting of skeletal muscle

> TABLE 45-1 Postural Abnormalities

Abnormality	Description	Cause	Possible Treatments*
Torticollis	Inclining of head to the affected side, in which the sternocleidomastoid muscle is contracted	Congenital or acquired condition	Surgery, heat, support, or immobilization, depending on cause and severity, gentle range of motion
Lordosis	Exaggeration of anterior convex curve of lumbar spine	Congenital condition Temporary condition (e.g., pregnancy)	Spine-stretching exercises (based on cause)
Kyphosis	Increased convexity in curvature of thoracic spine	Congenital condition Rickets, osteoporosis Tuberculosis of the spine	Spine-stretching exercises, sleeping without pillows, use of bed board, bracing, spinal fusion (based on cause and severity)
Kypholordosis	Combination of kyphosis and lordosis	Congenital condition	Similar to methods used in kyphosis or lordosis (based on cause) Immobilization and surgery (based on cause and severity)
Scoliosis	Lateral "S" curvature of spine, unequal heights of hips and shoulders	Congenital condition Poliomyelitis Spastic paralysis Unequal leg length	Immobilization and surgery (based on age, cause, and severity)
Kyphoscoliosis	Abnormal anteroposterior and lateral curvature of spine	Congenital condition Poliomyelitis Cor pulmonale	Immobilization and surgery (based on cause and severity)
Congenital hip dysplasia	Hip instability with limited abduction of hips and, occasionally, adduction contractures (head of femur does not articulate with acetabulum because of abnormal shallowness of acetabulum)	Congenital condition (more common with breech deliveries)	Maintenance of continuous abduction of the thigh so that head of femur presses into the centre of acetabulum Abduction splints, casting, surgery
Knock-knee (genu valgum)	Legs curved inward so that knees come together as person walks	Congenital condition Rickets	Knee braces, surgery if not corrected by growth
Bowlegs (genu varum)	One or both legs bent outward at knee, which is normal until two to three years of age	Congenital condition Rickets	Slowing rate of curving if not corrected by growth With rickets, increase of vitamin D, calcium, and phosphorus intake to normal ranges
Clubfoot	95%: medial deviation and plantar flexion of foot (equinovarus) 5%: lateral deviation and dorsiflexion (calcaneovalgus)	Congenital condition	Casts, splints such as Denis-Browne splint, and surgery (based on degree and rigidity of deformity)
Footdrop	Inability to dorsiflex and evert foot because of peroneal nerve damage	Congenital condition Trauma Improper position of a patient who is immobilized	None (cannot be corrected) Prevention through physiotherapy Bracing with ankle-foot orthotic
Pigeon-toes (metatarsus adductus or metatarsus varus)	Internal rotation of forefoot or entire foot, common in infants, often accompanied by development dysplasia of the hip	Congenital condition Habit	Growth, wearing reversed shoes, casting, bracing

*Severity of the condition and its cause will dictate treatment, which must be individualized.

groups, with increasing disability and deformity (McCance & Huether, 2010).

Damage to the Central Nervous System. Damage to any component of the central nervous system that regulates voluntary movement results in impaired body mobility. The motor strip in the cerebral cortex can be damaged by trauma from a head injury, ischemia from a stroke or brain attack (cerebrovascular accident), hemorrhage, tumour, or bacterial infection such as meningitis. Motor impairment is directly

related to the amount of destruction of the motor strip. For example, a person with a right-sided cerebral hemorrhage will likely have destruction of the right motor strip and hence have left-sided **hemiplegia** (muscle paralysis) or **hemiparesis** (muscle weakness). Trauma to the spinal cord also impairs mobility. A common trauma is transection of the spinal cord in which motor fibres are cut. A complete transection will likely result in a bilateral loss of voluntary motor control below the level of the trauma. Injury above the first thoracic vertebrae

results in **quadriplegia** (also known as tetraplegia) (four-limb paralysis) and injury below that level results in **paraplegia** (two-limb paralysis).

Direct Trauma to the Musculoskeletal System.

Direct trauma to the musculoskeletal system can result in bruises, contusions, sprains, and fractures. A **fracture** is a disruption of bone tissue continuity. Fractures most commonly result from direct external trauma but can also occur as a consequence of some deformity of the bone (e.g., **pathological fractures** of osteoporosis, Paget's disease, metastatic cancer, or osteogenesis imperfecta). Young children are usually able to form new bone more easily than adults and, as a result, have few complications after a fracture. Treatment often includes positioning the fractured bone in proper alignment and immobilizing it to promote healing and restore function. Even this temporary immobilization can result in some **muscle atrophy**, loss of tone, and joint stiffness. After the fracture has healed, physiotherapy may be required to regain functional losses.

Nursing Knowledge Base

Mobility-Immobility

A full understanding of mobility requires more than an overview of body mechanics and of the regulation of movement by the musculoskeletal and nervous systems. You must also know how mobility and immobility affect the systems of the body and the psychosocial and developmental aspects of patients.

Mobility refers to a person's ability to move about freely, and **immobility** refers to the inability to move about freely. Mobility and immobility are best understood as the end points of a continuum, with many degrees of partial mobility in between. Some patients move back and forth on this continuum, but for other patients, immobility is absolute and continues indefinitely. The terms *bed rest* and *impaired physical mobility* are frequently used when discussing patients on the mobility-immobility continuum.

Bed rest is an intervention that restricts patients to bed for therapeutic reasons. Nurses and physicians most often prescribe this intervention. Patients with a wide variety of conditions are placed on bed rest. The general objectives of bed rest are as follows:

- To reduce physical activity and the oxygen needs of the body
- To reduce pain, including postoperative pain, and the need for large doses of analgesics
- To promote safety for patients recovering from the effects of anaesthetics or who are sedated
- To allow patients who are ill or debilitated to rest
- To allow patients who are exhausted the opportunity for uninterrupted rest

The duration of bed rest depends on the illness or injury and the patient's prior state of health.

Impaired physical mobility is defined by the North American Nursing Diagnosis Association as a state in which the individual experiences or is at risk of experiencing limitation of physical movement (Ackley & Ladwig, 2006). Alterations in the level of physical mobility can result from prescribed restriction of movement in the form of bed rest, physical restriction of movement because of external devices (e.g., a cast or skeletal traction), voluntary restriction of movement, or impairment of motor or skeletal function.

Periods of immobility or prolonged bed rest can cause major physiological, psychological, and social effects. These

effects can be gradual or immediate and vary from patient to patient. The greater the extent and the longer the duration of immobility, the more pronounced are the consequences. The patient with complete mobility restrictions is continually at risk for hazardous system-wide effects.

Systemic Effects of Immobility. All body systems work more efficiently with some form of movement. Exercise has been shown to have positive outcomes for all major systems of the body (see Chapter 35). Therefore, when mobility is altered, each body system is at risk for impairment. The severity of the impairment depends on the patient's overall health, degree and length of immobility, and age. For example, older adults with chronic illnesses develop pronounced effects of immobility more quickly than younger patients with the same immobility problem (Box 45-1).

Metabolic Changes. Endocrine metabolism, calcium resorption, and functioning of the gastrointestinal system are altered by changes in mobility.

The endocrine system, made up of hormone-secreting glands, helps to maintain and regulate vital functions such as response to stress and injury, growth and development, reproduction, ionic homeostasis, and energy metabolism. When injury or stress occurs, the endocrine system triggers a series of responses aimed at maintaining blood pressure and preserving life. The endocrine system is important in maintaining homeostasis. Tissues and cells live in an internal environment that the endocrine system helps regulate through maintenance of sodium, potassium, water, and acid-base balance. The endocrine system also helps regulate energy metabolism. The basal metabolic rate (BMR) is increased by thyroid hormone, and energy is made available to cells through the integrated action of gastrointestinal and pancreatic hormones (Copstead-Kirkhorn & Banasik, 2011).

Immobility disrupts normal metabolic functioning by decreasing the metabolic rate; altering the metabolism of carbohydrates, fats, and proteins; causing fluid, electrolyte, and calcium imbalances; and causing gastrointestinal disturbances such as decreased appetite and slowing of peristalsis. However, in the presence of an infectious process, patients who are immobilized may have an increased BMR as a result of fever or wound healing. Fever and repair of wounds increase cellular oxygen requirements (Copstead-Kirkhorn & Banasik, 2011).

A deficiency in calories and protein is characteristic of patients with a decreased appetite secondary to immobility. Poor nutritional intake can result in a deficiency in essential amino acids. Whereas essential amino acids cannot be made by the body and muscle is constantly being broken down and reformed, a deficiency in essential amino acids can contribute to muscle wasting. Weight loss, decreased muscle mass, and weakness are the result. When more nitrogen (the end product of amino acid breakdown) is excreted than is ingested in proteins, the body is said to have a **negative nitrogen balance**. Another metabolic change is calcium resorption (loss) from bones. As a result, urinary excretion of calcium increases because immobility causes the release of calcium into the circulation. Normally, the kidneys can excrete the excess calcium. However, if the kidneys are unable to respond appropriately, hypercalcemia results (Copstead-Kirkhorn & Banasik, 2011).

Decreased mobility also leads to decreased gastrointestinal motility, which in turn can cause a variety of impairments to gastrointestinal functioning. Difficulty in passing stools (constipation) is a common symptom, although pseudodiarrhea

BOX 45-1 NURSING STORY

Patient Rehabilitation

When Grace Lo was admitted to the inpatient rehabilitation unit, it was difficult for me to imagine her living independently in a condominium, driving her car, going out to lunch, shopping, or playing bridge with her friends. She looked so frail and tired, and she needed assistance with everything. Grace was a 66-year-old widow with a diagnosis of uterine cancer. After being diagnosed, Grace was started on chemotherapy to help shrink the size of the tumour before having surgery to remove it. She experienced side effects from the chemotherapy—*anemia and neutropenia*. Unfortunately, she also developed recurrent pneumonia and had been immobilized in the intensive care and oncology units for over five weeks.

When Grace was admitted to the rehabilitation unit, she was significantly deconditioned. She had never enjoyed exercising and was feeling regret about not maintaining her physical fitness before her cancer diagnosis. Her ability to complete her chemotherapy treatments depended on her regaining her strength, endurance, mobility, and independence for her ADLs. Grace was very motivated to work with the rehabilitation team, but she was also afraid. What if she couldn't get strong enough to finish her chemotherapy?

At the beginning of rehabilitation, Grace needed assistance from two people for all her transfers. She had a Foley catheter in place, and she fatigued quickly with minimal exertion. Her respiratory status had been compromised by recurrent pneumonia and her past behaviour of cigarette smoking. The first goal was to increase her upper and lower extremity strength for transferring from the bed to a commode at the bedside. It took a coordinated interdisciplinary approach to work on Grace's pace at exercising and her ability to practise ADLs independently. Once Grace was able to safely transfer from the bed with a one-person, minimally assisted standing pivot transfer, the team was able to focus on the goal of urinary continence. Because she had been immobilized for an extended period of time, Grace often felt lightheaded and dizzy when sitting at the bedside before a transfer. These experiences contributed to her feelings of apprehension about falling and to a loss of confidence. It was important to raise the head of Grace's bed in increments before attempting transfers to minimize postural hypotension. After two weeks of exercising and practice, Grace was continent, using the bathroom in her room. However, she still had a long way to go.

Four months after she had been discharged from rehabilitation, I heard my name being called. A fit-looking woman was calling out to me—I barely recognized a radiant Grace. She had continued outpatient rehabilitation and was exercising regularly. Grace excitedly told me that she had finished her last cycle of chemotherapy. Her computerized tomography (CT) scan showed that the tumour in her uterus had decreased in size and she no longer needed surgery. Grace told me that while the diagnosis of cancer scared her, the experiences of being immobilized and dependent on others for all her ADLs had "terrified" her. Her story reminded me of the impact of immobility on all aspects of a person's life and of the importance of setting small, attainable goals in promoting independence and hope.

may result from a fecal impaction (accumulation of hardened feces). This finding is not normal diarrhea, but rather liquid stool passing around the area of impaction (see Chapter 44). Left untreated, fecal impaction can result in a mechanical bowel obstruction that may partially or completely occlude the intestinal lumen, blocking normal propulsion of liquid and gas. The resulting fluid in the intestine produces distension and increases intraluminal pressure. Over time, intestinal

function becomes depressed, dehydration occurs, absorption ceases, and fluid and electrolyte disturbances worsen.

Respiratory Changes. Regular aerobic exercise is known to enhance respiratory functioning. Conversely, lack of movement and exercise places patients at higher risk for respiratory complications. Patients who have recently had surgery or are immobile are at high risk for developing pulmonary complications. The most common respiratory complications are **atelectasis** (collapse of alveoli) and **hypostatic pneumonia** (inflammation of the lung from stasis or pooling of secretions). Both conditions decrease oxygenation, prolong recovery, and add to the patient's discomfort (Black & Hawks, 2009). In atelectasis, secretions block a bronchiole or a bronchus, and the distal lung tissue (alveoli) collapses as the existing air is absorbed, producing hypoventilation. The site of the blockage determines the extent of atelectasis. A lung lobe or even a whole lung may collapse. At some point in the development of these complications, the patient's ability to cough productively declines proportionately. Ultimately, the distribution of mucus in the bronchi increases, particularly when the patient is in the supine, prone, or lateral position. Mucus accumulates in the dependent regions of the airways. Because mucus is an excellent medium for bacterial growth, hypostatic pneumonia may result.

Cardiovascular Changes. The cardiovascular system is also affected by immobilization. The three major changes are orthostatic hypotension, increased cardiac workload, and thrombus formation.

Orthostatic hypotension is a drop of 20 mm Hg or more in systolic blood pressure and of 10 mm Hg in diastolic blood pressure within three minutes of when the patient rises from a lying or sitting position to a standing position (Medow et al., 2008). Decreased circulating fluid volume, pooling of blood in the lower extremities, and decreased autonomic response occur when a patient is immobile. These factors result in decreased venous return, followed by a decrease in cardiac output, which is reflected by a decline in blood pressure (McCance & Huether, 2010).

As the workload of the heart increases, its oxygen consumption does as well. The heart therefore works harder and less efficiently during periods of prolonged rest. As immobilization increases, cardiac output falls, further decreasing cardiac efficiency and increasing workload.

Patients are also at risk for thrombus formation. A **thrombus** is an accumulation of platelets, fibrin, clotting factors, and the cellular elements of the blood attached to the interior wall of a vein or artery, sometimes occluding the lumen of the vessel (Figure 45-1). Three factors contribute to venous thrombus formation: (1) loss of integrity of the vessel wall (e.g., injury), (2) abnormalities of blood flow (e.g., slow blood flow in calf veins associated with bed rest), and (3) alterations in blood constituents (e.g., a change in clotting factors or increased platelet activity). These three factors are sometimes referred to as *Virchow's triad* (McCance & Huether, 2010). A dislodged venous thrombus, called an **embolus**, may travel through the circulatory system to the lungs and impair circulation and oxygenation. Venous emboli that travel to the lungs are called pulmonary emboli and may be life-threatening. More than 90% of all pulmonary emboli begin in the legs or pelvis (Copstead-Kirkhorn & Banaski, 2011).

Musculoskeletal Changes. The effects of immobility on the musculoskeletal system can include temporary or permanent impairment. Restricted mobility may result in loss of

Figure 45-1 Thrombus formation in a vessel.

endurance, strength, and muscle mass as well as decreased stability and balance. Other effects of restricted mobility affecting the skeletal system are impaired calcium metabolism and impaired joint mobility.

Muscle Effects. Muscle weakness and deconditioning always occur to some extent with prolonged immobility. Protein breakdown in the absence of exercise results in a loss of lean body mass, which is composed primarily of muscle. The effect of immobility on muscle may be apparent in a matter of days. The normal individual on bed rest loses muscle strength from baseline levels at a rate of 3% a day.

The term *disuse atrophy* or muscle atrophy has been used to describe the pathological reduction in normal size of muscle fibres after prolonged inactivity from bed rest, trauma, casting, or local nerve damage (McCance & Huether, 2010). The reduced muscle mass is unable to sustain activity without increased fatigue. Loss of endurance, decreased muscle mass and strength, and joint instability (see “Skeletal Effects” section) put patients at risk for falls.

Skeletal Effects. Immobilization causes two skeletal changes: impaired calcium metabolism and joint abnormalities. Bone resorption is increased when an individual is not weight-bearing on their bones, such as during prolonged bed rest. The bone tissue is less dense, or is atrophied, and **disuse osteoporosis** results, putting the patient at risk for pathological fractures. Bone resorption also causes calcium to be released in the blood, and hypercalcemia results.

Osteoporosis is a major health concern in Canada. Eighty percent of all fractures in women over 50 are related to osteoporosis. Fragility fractures are responsible for excess mortality and morbidity (Papaioannou et al., 2010). Although primary osteoporosis is different in origin from the osteoporosis that results from immobility, it is imperative for nurses to recognize that patients who are immobile may be at high risk for accelerated bone loss if they have primary osteoporosis. Important interventions for preventing disability in patients with primary

* BOX 45-2 PATIENT TEACHING

Patients With Osteoporosis

Objective

- Patient will identify strategies to prevent or limit the severity of osteoporosis.

Teaching Strategies

- Instruct patient (and caregiver, if present) on common risk factors and how to modify lifestyle (e.g., eliminating smoking, caffeine, alcohol).
- Teach patient and caregiver the current recommended dietary allowances for calcium and vitamin D, and review foods high in calcium and vitamin D.
- Instruct patient and caregiver to do appropriate types of weight-bearing exercises as recommended by the physician or physiotherapist to prevent injury or fractures.
- Teach patient and caregiver about safety, fall prevention, and strategies to create a safe home environment.
- Instruct patient and caregiver in self-administration of appropriate medication as ordered by the physician.
- Foster a positive self-image in the patient by providing realistic yet optimistic and positive feedback about changes in the patient's appearance and mobility.

Evaluation

- Patient and caregiver identify strategies to modify the patient's lifestyle, such as stopping smoking, reducing caffeine or alcohol intake, or increasing dietary calcium.
- Patient and caregiver identify foods high in calcium and vitamin D.
- Patient and caregiver demonstrate appropriate weight-bearing exercises.
- Patient and caregiver identify safety strategies to prevent falls.
- Patient and caregiver demonstrate appropriate knowledge about medications.
- Patient and caregiver express positive but realistic feedback regarding the effects of disease.

osteoporosis who become immobilized include early patient evaluation, and consultation with and referral to physicians, dietitians, occupational therapists, and physiotherapists. For the patient with osteoporosis, the goal is to maintain independence with ADLs. Assistive ambulatory devices, adaptive clothing, and safety bars may assist the patient with maintaining independence. Patient teaching should focus on limiting the severity of the disease through diet and activity (Box 45-2).

Immobility can lead to a **joint contracture**, which is an abnormal condition characterized by fixation of a joint. It is caused by disuse, atrophy, and shortening of the muscle fibres. When a contracture occurs, the joint cannot obtain full ROM. Contractures may leave a joint in a nonfunctional position (Figure 45-2) and possibly be permanent. Early prevention of contractures is key, as they can begin to form after only eight hours of immobility in the older patient (Fletcher, 2005).

One common and debilitating contracture is **footdrop** (Figure 45-3 and Figure 45-4). When **footdrop** occurs, the foot is permanently fixed in plantar flexion and is unable to dorsiflex. Ambulation is difficult with the foot in this position because the patient is unable to lift the toes off the ground. Footdrop can be associated with a variety of etiologies, including prolonged bed rest, peroneal nerve damage, peripheral neuropathy, and cerebral vascular accidents (strokes).

Figure 45-2 A contracture of the joints in the fingers. **Source:** Sorrentino, S. A., Wilk, M. J., & Newmaster, R. (2009). *Mosby's Canadian textbook for the support worker* (2nd ed., p. 429, Fig 24-1). Toronto: Elsevier.

Figure 45-3 Footdrop. The ankle is fixed in plantar flexion. Normally, the ankle is able to flex (dotted line), which eases walking.

Figure 45-4 Patient with bilateral footdrop.

Urinary Elimination Changes. The patient's urinary elimination is altered by immobility. In the upright position, urine flows out of the renal pelvis and into the ureters and bladder because of gravitational forces. When the patient is recumbent or flat, the kidneys and the ureters move toward a more level plane. Urine formed by the kidney must enter the bladder unaided by gravity. Because the peristaltic contractions of the ureters are insufficient to overcome gravity, the renal pelvis may fill before urine enters the ureters. This condition, called **urinary stasis**, increases the risk of urinary tract infection and renal calculi (see Chapter 43). Renal calculi are calcium stones that lodge in the renal pelvis and pass through the ureters. Patients who are immobile are at risk for calculi because of urinary stasis as well as altered calcium metabolism and the resulting hypercalcemia.

As the period of immobility continues, fluid intake can diminish, and this increases the risk for dehydration. As a result of decreased fluid intake, urinary output may decline around the fifth or sixth day after immobilization and the urine is often highly concentrated. This concentrated urine increases the risk for calculi formation and infection. Patients who are immobile may also have less access to bathing equipment and be unable to perform adequate perineal hygiene, which may also increase the risk of urinary tract contamination by *Escherichia coli* bacteria.

Patients who are immobile may not be getting up to use the bathroom or even a bedside commode. Voiding on a bedpan or using a urinal does not provide the usual sensory stimulation to void, nor does it allow gravity to act on the bladder sphincter. Thus, patients may be unable to void at all or completely. There may be residual urine in the bladder, which increases the risk of infection. There may be complete urinary retention, which necessitates catheterization. Both intermittent catheterization and indwelling catheters increase the risk of urinary tract infections in these patients.

Integumentary Changes. Individuals who have impaired movement and/or sensation are at risk for the development of pressure ulcers. A **pressure ulcer** is an impairment of the skin as a result of prolonged ischemia (decreased blood supply) in tissues (see Chapter 46). Ischemia develops when the pressure on the skin is greater than the pressure inside the small peripheral blood vessels supplying blood to the skin. Adequate blood flow is necessary to supply oxygen and nutrients for tissue metabolism and the elimination of metabolic wastes.

People who are conscious and have voluntary muscle control and normal perception of pressure perceive decreased circulation to tissue. They change positions regularly to increase circulation to tissue and prevent the formation of pressure ulcers. Individuals with impaired sensation or mobility may require assistance to regularly reposition themselves, to avoid the development of pressure ulcers. Pressure ulcers tend to develop over bony prominences. The location of bony prominences, and hence the skin most at risk for breakdown, varies depending on patient positioning, but individuals require frequent position changes, whether they are lying down or sitting.

safety alert Implement a comprehensive skin care program to prevent skin breakdown in all patients, from neonates to older adults. Effective skin care programs include accurate and consistent assessment and documentation as well as interventions to protect the skin (e.g., turn the patient every two hours and use mechanical devices such as lifts when you need to move the patient; RNAO, 2005b).

Psychosocial Effects of Immobility. Immobilization can contribute to decreased social interaction, social isolation, sensory deprivation, loss of independence and role changes. These in turn may lead to emotional reactions, behavioural responses, sensory alterations, and changes in coping. These changes are different for each patient.

Patients who are immobilized can become depressed because of changes in role, self-concept, and other factors. Depression is an affective disorder characterized by exaggerated feelings of sadness, melancholy, dejection, worthlessness, emptiness, and hopelessness out of proportion to reality. Depression can result from worrying about present and future levels of health, finances, and family needs. Because immobilization removes the patient from a daily routine, he or she has more time to worry about disability. Worrying can in turn quickly increase the patient's depression, causing withdrawal. By assessing behavioural changes throughout a patient's restricted mobility, you will be better equipped to identify changes in self-concept, recognize early signs of depression, and develop nursing interventions.

Behavioural changes resulting from immobilization vary widely, depending on the patient. Common behavioural changes are hostility, belligerence, giddiness, fear, and anxiety. Early in the nursing process you should interview the patient's family about normal behavioural patterns to gain baseline data. If unexpected behaviours are observed later, you can intervene to reduce the effects of immobilization on the patient's behavioural patterns.

Sleep-wake alterations in the patient who is immobile may occur from nursing care or changes in habit or environment. Disruption of normal sleeping patterns can further cause behavioural changes and contribute to delirium. Nursing interventions should be used to ensure that the patient receives sufficient sleep (see Chapter 40). The patient who is on bed rest and is able to change position during sleep does not require continuous physical nursing care. Unless other treatment activities are required during the night, the care plan for the physiologically stable patient on bed rest should provide for uninterrupted sleep.

Long-term immobility or bed rest can affect usual coping patterns. Such a patient may withdraw and become passive. The passive patient allows nurses to provide care but is not interested in increasing independence or involvement in care. Early in the care of a patient who is immobile, you should assess the patient's normal coping mechanisms in order to design a nursing care plan that will accommodate the patient's coping abilities or help the patient develop new ones.

Developmental Changes. Developmental changes associated with immobility tend to occur most commonly in very young children and in older adults. The immobilized young or middle-aged adult who has been healthy may experience few, if any, developmental changes. However, exceptions exist, and patients must be fully assessed for developmental implications. One exception might be a mother who has complications at childbirth and as a result cannot interact with the newborn infant as expected.

Infants, Toddlers, and Preschoolers. The newborn infant's spine is flexed and lacks the anteroposterior curves of the adult (see Chapter 22). As the baby grows, musculoskeletal development permits support of weight for standing and walking. Posture is awkward because the head and upper trunk are carried forward. Because body weight is not evenly distributed along a line of gravity, posture is off balance, and falls occur often. When the infant, toddler, or preschooler is

immobilized, it is usually because of trauma or the need to correct a congenital skeletal abnormality. Prolonged immobilization can delay the child's gross motor skills, intellectual development, or musculoskeletal development. Nurses caring for immobilized children should plan activities that provide physical and psychosocial stimuli.

Adolescents. The adolescence stage is usually initiated by a tremendous growth spurt (see Chapter 22). Growth is frequently uneven. Prolonged immobilization may alter adolescent growth patterns. In addition, the adolescent may lag behind peers in gaining independence. When immobilization occurs, social isolation will likely be a concern for this age group.

Adults. An adult who has correct posture and body alignment feels good, looks good, and generally appears self-confident. The healthy adult also has the necessary musculoskeletal development and coordination to carry out ADLs (see Chapter 23). When periods of prolonged immobility occur, however, all physiological systems are at risk. In addition, the role of the adult may change with regard to the family or social structure. The adult may lose identity associated with a job.

Older Adults. Aging is normally associated with a progressive loss of total bone mass (strength), muscle strength, and aerobic capacity. Some of the possible causes of this loss are decreased physical activity, hormonal changes, and actual bone resorption. Older adults may walk more slowly, take smaller steps, and appear less coordinated. Thus balance is impaired, and they are at greater risk for falls and injuries (see Chapter 24). The outcomes of a fall include not only possible injury but also hospitalization, loss of independence, and psychological effects.

Older adults may experience functional-status changes secondary to hospitalization and altered mobility status (Box 45-3). They may become more physically dependent. In some older adults, immobilization can occur progressively such as from a degenerative disease or chronic illness. In others, immobilization can occur suddenly such as after a stroke. When providing nursing care for an older adult, you should develop a care plan that encourages the patient to perform as many self-care activities as possible, thereby maintaining the highest level of mobility and functionality. Nurses may inadvertently contribute to a patient's immobility by providing unnecessary help with activities such as bathing and transferring.

Critical Thinking

Critical thinking requires you to combine knowledge, experience, patient data, and professional standards. Each of these sources must be integrated into the nurse's diagnosis and care plan for the patient with impaired mobility (Figure 45-5). A creative approach can also be helpful. Best Practice Guidelines such as those developed by the Registered Nurses' Association of Ontario (RNAO) provide valuable guides for managing complications associated with immobility. In addition, many health care facilities have standards of practice related to the lifting and transferring of patients and the prevention of falls and pressure sores.

Nursing Process for Impaired Body Alignment and Mobility

By applying the nursing process and using a critical thinking approach, you can develop individualized care plans for patients with mobility impairments or risk for immobility. The

► BOX 45-3

Hazards of Immobility in Hospitalized Older Adults

For many older adults, admission to the hospital often results in functional decline. Older adults can quickly regress to a dependent state. Rapid intervention of an interdisciplinary health team is required to maintain the patient's functional capacity.

Usual aging is associated with decreased muscle strength and aerobic capacity. Ordering bed rest for patients without sufficient ambulation leads to a loss of mobility and functional decline. Immobility causes weakness, fatigue, and an increased risk for falls. It also results in shallow breathing, which may lead to pneumonia. Inadequate turning or repositioning of a patient who is immobile can result in skin breakdown and pressure ulcers.

Catheter use and improper pericare can lead to urinary tract infections. Older adults are prone to nosocomial infections (infections obtained in the health care environment) because they often have compromised immune systems. Infections, as well as medications, treatments, and translocation, often cause confusion in older adults.

Hospitalization affects the nutritional status of the older adult. Limited access to fluids causes dehydration; conversely, fluid overload occurs from improper administration of intravenous (IV) fluids. Treatments and medications can cause fluid and electrolyte imbalances, contributing to confusion in the geriatric patient.

Finally, multiple interruptions and noise in the environment impair sleep, causing fatigue, depression, and confusion. Any of these factors may thrust vulnerable older adults into a state of irreversible functional decline.

aim of the care plan is to improve the patient's functional status, promote self-care, maintain psychological well-being, and reduce the hazards of immobility.

◆ Assessment

Nursing assessment is presented here in two sections: mobility and immobility. Both areas are usually assessed during the complete physical examination.

Mobility

Assessment of patient mobility focuses on ROM, gait, exercise and activity tolerance, and body alignment. When unsure of the patient's abilities, you should begin assessment of mobility with the patient in the most supportive position and move to higher levels of mobility according to the patient's tolerance. Generally, start assessing movement while the patient is lying, then proceed to assessing sitting positions in bed, transfers to chair, and, finally, gait. This sequence of assessment helps to protect the patient's safety.

Range of Motion. Range of motion (ROM) is the maximum amount of movement available at a joint in one of the four planes of the body: medial, sagittal, frontal, or transverse. The medial plane is a line through the axis of the body, separating the body into equal halves, a left side and a right side. The sagittal plane is any plane parallel to the medial plane. The frontal plane passes through the body from side to side and divides the body into front and back. The transverse plane is a horizontal line that divides the body into upper and lower portions. The anatomical position is used as a reference when

Figure 45-5 Critical thinking model for mobility assessment.

describing the parts of the body as they relate to each other (Figure 45-6).

Joint mobility is limited by ligaments, muscles, and the nature of the joint. Joint movements are described using the following terms:

- **Flexion and extension:** Flexion is decreasing the angle between two adjoining bones (bending of the joint); extension is increasing the angle between two adjoining bones (extending the joint). Examples of affected body parts are the fingers, elbows, and knees.
- **Hyperextension:** This is movement of a body part beyond its normal resting extended position.
- **Dorsiflexion and plantar flexion:** Dorsiflexion is the flexion of toes and foot upward; plantar flexion is the bending of toes and foot downward.
- **Abduction and adduction:** Abduction is movement of an extremity away from the midline of the body; adduction is movement of an extremity toward the midline of body (e.g., arms, fingers, and legs).
- **Eversion and inversion:** Eversion is the turning of a body part away from the midline; inversion is the turning of a body part toward the midline (e.g., feet).
- **Pronation and supination:** Pronation is movement of a body part so that the front or ventral surface faces downward; supination is movement of a body part so that the front or ventral surface faces upward (e.g., hands, forearm).

- **Internal and external rotation:** Internal rotation is rotation of the joint inward; external rotation is rotation of the joint outward (e.g., hip).
- **Circumduction:** This is the circular movement of a limb in a cone-shaped manner (e.g., shoulder).

When assessing ROM, physically examine the patient for stiffness, swelling, pain, limited movement, and unequal movement, and ask the patient whether any of these features are present. Assessment of ROM is important as a baseline

Figure 45-6 Planes of the body.

measurement to compare and evaluate whether loss in joint mobility has occurred. Patients whose mobility is restricted require ROM exercises to reduce the hazards of immobility, such as contractures. Thus, it is important to assess the type of ROM exercise a patient can perform. ROM exercises may be active (the patient is able to move all joints through his or her ROM unassisted), passive (the patient is unable to move independently, and the nurse moves each joint through its ROM), or somewhere in between (Table 45-2). With a patient who is weak, you may provide support while the patient performs most of the movement, or the patient may be able to move some joints actively while you passively move others. In general, exercises should be as active as health and mobility allow.

Body Alignment. Assessment of body alignment can be carried out with the patient lying, sitting, or standing. This assessment has the following objectives:

- To determine normal physiological changes in body alignment resulting from growth and development for each individual patient.
- To identify deviations in body alignment caused by poor posture.
- To provide opportunities for patients to observe their posture.
- To identify learning needs of patients for maintaining correct body alignment.
- To identify trauma, muscle damage, or nerve dysfunction.
- To obtain information about other factors contributing to poor alignment, such as fatigue, malnutrition, and psychological problems.

Lying. The first step in assessing body alignment is to put the patient at ease so that unnatural or rigid positions are not assumed. When assessing the body alignment of a patient who is immobilized or unconscious, pillows and positioning supports should be removed from the bed and the patient placed

TABLE 45-2 Range-of-Motion Exercises

Body Part	Type of Joint	Type of Movement	Range (Degrees)	Primary Muscles
Neck, cervical spine	Pivotal	Flexion: Bring chin to rest on chest.	45	Sternocleidomastoid
		Extension: Return head to erect position.	45	Trapezius
		Hyperextension: Bend head back as far as possible.	10	Trapezius
		Lateral flexion: Tilt head as far as possible toward each shoulder.	40–45	Sternocleidomastoid
		Rotation: Turn head as far as possible along transverse plane to look to each side.	70–90	Sternocleidomastoid, trapezius

► TABLE 45-2 Range-of-Motion Exercises—cont'd

Body Part	Type of Joint	Type of Movement	Range (Degrees)	Primary Muscles
Shoulder	Ball and socket	Flexion: Raise arm from side position forward to position above the head.	180	Coracobrachialis, biceps brachii, deltoid, pectoralis major
		Extension: Return arm to position at side of the body.	45–60	Latissimus dorsi, teres major, triceps brachii
		Hyperextension: Move arm behind body, keeping elbow straight.	180 45–60	Latissimus dorsi, teres major, deltoid
		Abduction: Raise arm to side to position above head with palm away from head.	180	Deltoid, supraspinatus
		Adduction: Lower arm sideways and across body as far as possible.	320	Pectoralis major
		Internal rotation: With elbow flexed, rotate shoulder by moving arm until thumb is turned inward and toward back.	90	Pectoralis major, latissimus dorsi, teres major, subscapularis
		External rotation: With elbow flexed, move arm until thumb is upward and lateral to head.	90	Infraspinatus, teres major, deltoid
Elbow	Hinge	Circumduction: Move arm in full circle. (Circumduction is a combination of all movements of the ball-and-socket joint.)	360	Deltoid, coracobrachialis, latissimus dorsi, teres major
		Flexion: Bend elbow so that lower arm moves toward its shoulder joint and the hand is level with the shoulder.	150	Biceps brachii, brachialis, brachioradialis
		Extension: Straighten elbow by lowering hand.	150	Triceps brachii

► TABLE 45-2 Range-of-Motion Exercises—cont'd

Body Part	Type of Joint	Type of Movement	Range (Degrees)	Primary Muscles
Forearm	Pivotal	Supination: Turn lower arm and hand so that the palm is up. Pronation: Turn lower arm so that the palm is down.	70–90 70–90	Supinator, biceps brachii Pronator teres, pronator quadratus
Wrist	Condyloid			
		Flexion: Move palm toward inner aspect of forearm.	80–90	Flexor carpi ulnaris, flexor carpi radialis
		Extension: Move fingers and hand posterior to midline.	80–90	Extensor carpi radialis brevis, extensor carpi radialis longus, extensor carpi ulnaris
		Hyperextension: Bring dorsal surface of hand back as far as possible.	80–90	Extensor carpi radialis brevis, extensor carpi radialis longus, extensor carpi ulnaris
		Abduction (radial deviation): Place hand with palm up and extend wrist laterally toward the thumb.	Up to 30	Flexor carpi radialis, extensor carpi radialis brevis, extensor carpi radialis longus
Fingers	Condyloid hinge	Adduction (ulnar deviation): Place hand with palm up and extend wrist medially toward the fifth finger.	30–50	Flexor carpi ulnaris, extensor carpi ulnaris
		Flexion: Make a fist.	90	Lumbricales, interosseus volaris, interosseus dorsalis
		Extension: Straighten fingers.	90	Extensor digiti quinti proprius, extensor digitorum communis, extensor indicis proprius
		Hyperextension: Bend fingers back as far as possible.	30–60	
		Abduction: Spread fingers apart.	30	Interosseus dorsalis
		Adduction: Bring fingers together.	30	Interosseus volaris

► TABLE 45-2 Range-of-Motion Exercises—cont'd

Body Part	Type of Joint	Type of Movement	Range (Degrees)	Primary Muscles
Thumb	Saddle	Flexion: Move thumb across palmar surface of hand.	90	Flexor pollicis brevis
		Extension: Move thumb straight away from hand.	90	Extensor pollicis longus, extensor pollicis brevis
		Abduction: Extend thumb laterally (usually done when placing fingers in abduction and adduction).	30	Abductor pollicis brevis
		Adduction: Move thumb back toward hand.	30	Adductor pollicis obliquus, adductor pollicis transverses
		Opposition: Touch thumb to each finger of the same hand.		Opponeus pollicis, opponeus digiti minimi
Hip	Ball and socket	Flexion: Move leg forward and up.	90–120	Psoas major, iliacus, sartorius
		Extension: Move leg back beside other leg.	90–120	Gluteus maximus, semitendinosus, semimembranosus
		Hyperextension: Move leg behind the body.	30–50	Gluteus maximus, semitendinosus, semimembranosus
		Abduction: Move leg laterally away from the body.	30–50	Gluteus medius, gluteus minimus
		Adduction: Move leg back toward medial position and beyond, if possible.	30–50	Adductor longus, adductor brevis, adductor magnus
		Internal rotation: Turn foot and leg toward other leg.	90	Gluteus medius, gluteus minimus, tensor fasciae latae
		External rotation: Turn foot and leg away from other leg.	90	Obturatorius internus, obturatorius externus
		Circumduction: Move leg in a circle.		Psoas major, gluteus maximus, gluteus medius, adductor magnus

Continued

► TABLE 45-2 Range-of-Motion Exercises—cont'd

Body Part	Type of Joint	Type of Movement	Range (Degrees)	Primary Muscles
Knee		Flexion: Bring heel back toward back of thigh.	120–130	Biceps femoris, semitendinosus, semimembranosus, sartorius
		Extension: Return leg to the floor.	120–130	Rectus femoris, vastus lateralis, vastus medialis, vastus intermedius
Ankle		Dorsiflexion: Move foot so that toes are pointed upward.	20–30	Tibialis anterior
		Plantar flexion: Move foot so that toes are pointed downward.	45–50	Gastrocnemius, soleus
Foot		Inversion: Turn sole of foot medially.	10 or less	Tibialis anterior, tibialis posterior
		Eversion: Turn sole of foot laterally.	10 or less	Peroneus longus, peroneus brevis
Toes		Flexion: Curl toes downward.	30–60	Flexor digitorum, lumbricalis pedis, flexor hallucis brevis
		Extension: Straighten toes.	30–60	Extensor digitorum longus, extensor digitorum brevis, extensor hallucis longus
		Abduction: Spread toes apart.	15 or less	Abductor hallucis, interosseus dorsalis
		Adduction: Bring toes together.	15 or less	Adductor hallucis, interosseus plantaris

in the supine position. Observe for the following signs of good body alignment:

- The head is midline.
- The shoulders and hips are straight and parallel.
- The thighs are relaxed and legs are slightly and equally externally rotated.
- The ankles are slightly plantar flexed.
- The arms lie at the sides with elbows and fingers slightly flexed.
- The person appears comfortable.

Assessment of body alignment should also be done in the lateral position. Again, all positioning supports should be removed from the bed except for the pillow under the head, and the body should be supported by an adequate mattress (Figure 45-7). This position allows for full view of the spine and back and will help provide other baseline body alignment

Figure 45-7 Lateral lying position for assessment of body alignment.

data, such as whether the patient can remain positioned without aid. The vertebrae should be aligned, and the position should not cause discomfort.

Sitting. Assess body alignment when the patient is sitting in a chair or wheelchair by observing for the following (Figure 45-8):

Figure 45-8 Correct body alignment when sitting. The patient's feet are flat on the floor, the calves do not touch the chair, and the back is straight and against the back of the chair. **Source:** Sorrentino, S. A., Wilk, M.J. & Newmaster, R. (2009). *Mosby's Canadian textbook for the support worker* (2nd ed., p. 412, Fig 23-20). Toronto: Elsevier.

- The head is erect, and the neck and vertebral column are in straight alignment.
- The body weight is evenly distributed on the buttocks and thighs.
- The thighs are parallel and in a horizontal plane.
- Both feet are supported on the floor or on wheelchair footrests. With patients who are short, a footstool is used and the ankles are comfortably flexed.
- A 2.5- to 5-cm space is maintained between the edge of the seat and the popliteal space on the posterior surface of the knee. This space ensures that no pressure is on the popliteal artery or nerve to decrease circulation or impair nerve function.
- The patient's forearms are supported on the armrest, in the lap, or on a table in front of the chair.

It is particularly important to assess alignment when sitting if the patient has muscle weakness, muscle paralysis, or nerve damage. Proper alignment while sitting reduces the risk of musculoskeletal system damage. The patient with severe respiratory disease may assume a posture of leaning on a table in front of the chair in an attempt to breathe more easily.

Standing. When the patient is standing, check for the following signs of good body alignment:

- The head is erect and midline.
- When observed posteriorly, the shoulders and hips are straight and parallel.
- When observed posteriorly, the vertebral column is straight.
- When the patient is observed laterally, the head is erect and the spinal curves are aligned in a reversed "S" pattern. The cervical vertebrae are anteriorly convex, the thoracic vertebrae are posteriorly convex, and the lumbar vertebrae are anteriorly convex.
- When observed laterally, the abdomen is comfortably tucked in and the knees and ankles are slightly flexed. The person appears comfortable and does not seem conscious of the flexion of knees or ankles.
- The arms hang comfortably at the sides.
- The feet are placed slightly apart to achieve a base of support, and the toes are pointed forward.
- When the patient is viewed anteriorly, the centre of gravity is in the midline, and the line of gravity is from the middle

Figure 45-9 Correct body alignment when standing.

of the forehead to a midpoint between the feet. Laterally, the line of gravity runs vertically from the middle of the skull to the posterior third of the foot (Figure 45-9).

Gait. The term **gait** is used to describe a particular manner or style of walking. The gait cycle begins with the heel strike of one leg and continues to the heel strike of the other leg. Assessment of a patient's gait helps you to draw conclusions about balance, posture, safety, and ability to walk without assistance. The mechanics of human gait involve coordination of the skeletal, neurological, and muscular systems of the human body.

Exercise and Activity Tolerance. Exercise is physical activity for conditioning the body, improving health, and maintaining fitness. It can be used as therapy to correct a deformity or to restore the overall body to a maximal state of health. When a person exercises, physiological changes occur in body systems (see Chapter 35).

Assessment of the patient's energy level includes assessment of the physiological effects of exercise and activity tolerance. **Activity tolerance** is the type and amount of exercise or work that a person is able to perform. It is important to assess a patient's activity tolerance when planning activities for the patient such as walking or ADLs such as bathing. To assess activity tolerance, you will need data from physiological, emotional, and developmental domains (see Chapter 35). This assessment is applicable in all clinical settings and can be quickly completed.

When activity begins, you should monitor patients for symptoms such as dyspnea, fatigue, chest pain, or change in vital signs from baseline. Some patients may be unable to sustain activity because the energy needed to complete the activity creates fatigue and generalized weakness. Even simple tasks such as eating or moving in bed may need to be monitored. If you note decreased activity tolerance, carefully assess the time needed by the patient to recover. A decreasing recovery time may indicate improved activity tolerance.

People who are depressed, worried, or anxious are frequently unable to tolerate exercise. Patients who are depressed are usually not motivated to participate. Patients who are worried or anxious tire easily because they expend a great deal of energy in states of worry and anxiety. Thus, they may experience physical and emotional exhaustion.

Developmental changes also affect tolerance for activity. As the infant enters the toddler stage, the activity level increases

and the need for sleep declines. The child entering preschool or primary grades expends mental energy in learning and may require more rest after school or before strenuous play. The adolescent going through puberty may require more rest because much of the body's energy is expended for growth and hormone changes.

Changes may still occur through the adult years, but many of these changes are related to work and lifestyle choices. Pregnancy may decrease a woman's energy tolerance, especially during the first and third trimesters. Hormonal changes and fetal development use body energy, and the woman may be unable or unmotivated to carry out physical activities. During the last trimester, fetal development consumes a great deal of the mother's energy, and the size and location of the fetus may limit the mother's ability to take a deep breath, resulting in less oxygen being available for physical activities.

As the person grows older, activity tolerance changes. Muscle mass is reduced, posture changes, and the composition of bones is altered. Changes often occur in the cardiopulmonary system, such as decreased maximum heart rate and decreased lung compliance, that affect the intensity of exercise. The older adult may still exercise but will do so at a reduced intensity. The more inactive a patient becomes, the more pronounced these activity changes are.

Immobility

Physiological Assessment. To assess the patient for hazards of immobility, you will need to perform a head-to-toe physical assessment (see Chapter 31). The nursing assessment should focus on certain physiological areas, as well as on the patient's psychosocial and developmental dimensions. The physiological hazards of immobility that may be identified during a nursing assessment are summarized below and in Table 45-3.

Metabolic System. When assessing metabolic functioning, use **anthropometric measurements** (measures of height, weight, and skin fold thickness) to evaluate muscle atrophy. In addition, you may need to analyze intake and output records to determine whether a fluid imbalance exists (see Chapter 39). Dehydration and edema can increase the rate of skin breakdown in a patient who is immobilized. Monitoring laboratory data such as electrolytes, serum protein (albumin and total protein) levels, and blood urea nitrogen can help you determine metabolic functioning.

Assessment of wound healing and monitoring of food intake and elimination patterns will help to determine altered gastrointestinal functioning and potential metabolic problems. If a patient who is immobile has a wound, the rate of healing indicates how well nutrients are being delivered to tissues. Normal progression of healing indicates that metabolic needs of injured tissues are being met. Anorexia occurs commonly in patients who are immobilized. The patient's food intake should be assessed before the meal tray is removed to determine the amount eaten. Nutritional imbalances can be avoided if you assess the patient's dietary patterns and food preferences early in immobilization (see Chapter 42).

Respiratory System. A respiratory assessment should be performed at least every two hours for patients with restricted activity. Inspect chest wall movements during the full inspiratory-expiratory cycle. If a patient has an atelectatic area, chest movement may be asymmetrical. In addition, auscultate the entire lung region to identify diminished breath sounds, crackles, or wheezes. Auscultation should focus on the

► TABLE 45-3

Physiological Hazards of Immobility

System	Assessment Techniques	Abnormal Findings
Metabolic	Inspection	Slowed wound healing, abnormal laboratory data
	Inspection Anthropometric measurements (mid-upper arm circumference, triceps skinfold measurement)	Muscle atrophy Decreased amount of subcutaneous fat
Respiratory	Palpation Inspection	Generalized edema Asymmetrical chest wall movement, dyspnea, increased respiratory rate
	Auscultation	Crackles, wheezes, decreased air entry
Cardiovascular	Auscultation Auscultation, palpation	Orthostatic hypotension Increased heart rate, third heart sound, weak peripheral pulses
	Inspection	Dependent edema in feet and legs (if seated) and in sacrum (if lying)
Musculoskeletal	Inspection, palpation	Decreased range of motion, erythema, increased diameter in calf or thigh
	Palpation Inspection	Joint contracture Activity intolerance, muscle atrophy, joint contracture
Elimination	Inspection	Decreased urine output, cloudy or concentrated urine, decreased frequency of bowel movements
	Palpation	Distended bladder and abdomen
Skin	Auscultation Inspection, palpation	Decreased bowel sounds Break in skin integrity

dependent lung fields because pulmonary secretions tend to collect in these lower regions. Perform a complete respiratory assessment to identify the presence of secretions and to determine nursing interventions necessary for optimal respiratory function.

Cardiovascular System. Cardiovascular assessment of the patient who is immobile includes blood pressure monitoring, evaluation of apical and peripheral pulses, and observation for signs of venous stasis (e.g., edema and poor wound healing). All patients should have their vital signs monitored during the first few attempts at sitting or standing.

When getting the patient from a supine position into a chair, move the patient gradually. When performing this procedure, assess and document orthostatic changes. First, obtain baseline

blood pressure and pulse measurements with the patient in the supine position, and then assist the patient to a position sitting at the side of the bed. The patient should remain sitting for three minutes before you take the blood pressure and pulse. Remain with the patient in a sitting position and continually monitor the patient for dizziness or lightheadedness. If the patient has no dizziness or drop in blood pressure (≥ 20 mm Hg systolic or 10 mm Hg diastolic), assist the patient to a standing position and retake the blood pressure and pulse immediately when the patient stands and again after three minutes of standing. The patient should be monitored closely for dizziness throughout this procedure. The longer the period of immobility, the greater the risk of hypotension when the patient stands (Copstead-Kirkhorn & Banasik, 2011).

You will also need to assess the apical and peripheral pulses. Recumbency increases cardiac workload and pulse rate. In some patients, particularly older adults, the heart may not tolerate the increased workload, and a form of cardiac failure may develop. A third heart sound, heard at the apex with the bell of the stethoscope, can be an early indication of heart failure. Monitoring of peripheral pulses will enable you to evaluate the heart's ability to pump blood. The absence of a peripheral pulse in the lower extremities, particularly one that was previously present, should be documented and reported to the physician.

Edema may develop in patients who have had injury or whose heart is unable to handle the increased workload of bed rest. Because edema moves to dependent body regions, assessment of the patient who is immobile should include the sacrum, legs, and feet. If the heart is unable to tolerate the increased workload, peripheral body regions, such as the hands, feet, nose, and earlobes, will be colder than central body regions. Edema can be caused by other means such as renal impairment and certain medications such as steroids. The nurse must look for other sources of edema beyond heart failure and immobility.

Finally, assess the venous system, because deep vein thrombosis (DVT) is a hazard of restricted mobility. To assess for a DVT, remove the patient's elastic stockings or sequential compression devices (SCDs) every eight hours and observe the calves for redness, warmth, and tenderness. Homans' sign, or calf pain on dorsiflexion of the foot, was once used as an indicator of a probable thrombus, but this sign is not always present. Checking for Homans' sign may be contraindicated in a suspected DVT, as some investigators think that vigorous dorsiflexion may dislodge the thrombus. In addition, calf circumference should be measured daily. To do this, mark a point on each calf 10 cm from the midpatella. The circumference is measured each day using the mark for placement of the tape measure. Unilateral increases in calf diameter can be an early indication of thrombosis. Because DVTs can also occur in the thigh, you should measure the thighs daily if the patient is prone to thrombosis. In many patients, DVTs can be prevented by active exercise and compression devices in conjunction with prescribed anticoagulant treatment.

If a patient has a DVT, an embolus can dislodge and travel to the lung, causing a pulmonary embolism (PE). The signs and symptoms of PE vary depending on the size of the embolus and hence the extent of occlusion of the pulmonary vasculature. A massive PE can cause sudden and profound shock, including hypotension, tachycardia, tachypnea, hypoxia, and chest pain. Individuals can die within hours if the PE is not identified and treated quickly (McCance & Huether, 2010).

Musculoskeletal System. Major musculoskeletal abnormalities that may be identified during nursing assessment include decreased muscle tone and strength, loss of muscle mass, and contractures. The anthropometric measurements described previously may indicate losses in muscle tone and muscle mass.

Early assessment of ROM is important as a baseline against which later measurements can be compared to evaluate whether a loss in joint mobility has occurred. ROM can be measured with a goniometer.

Disuse osteoporosis cannot be identified by physical assessment. However, patients on prolonged bed rest, postmenopausal women, patients taking steroids, and people with increased serum and urine calcium levels have a greater risk for bone demineralization. The risk of disuse osteoporosis should be considered when planning nursing interventions. Not only may falls result in injury but they may also occur because of pathological fractures secondary to osteoporosis. Patients who are at risk for osteoporosis should have their diet assessed for calcium intake (Papaioannou et al., 2010).

Elimination System. The patient's elimination status should be evaluated on each shift, and total intake and output should be evaluated every 24 hours and compared over time. You should determine that the patient is receiving the correct amount and type of fluids orally or parenterally (see Chapter 39).

Assessment of elimination status should also include an analysis of dietary and fluid intake, review of medications, monitoring of the frequency and consistency of bowel movements, and an abdominal examination (RNAO, 2011) (see Chapter 44). With accurate assessment, you will be able to intervene before constipation and fecal impaction occur.

Integumentary System. Early identification of high-risk patients and their risk factors can aid you in preventing pressure ulcers (see Chapter 46). Continually assess the patient's skin for breakdown and colour changes such as pallor or redness. The skin should be observed when the patient is turned, during hygiene measures, and when elimination needs are provided for. At a minimum, assessment should occur every two hours (RNAO, 2005b).

Psychosocial Assessment. Many alterations in psychological, sociocultural, cognitive, and developmental functioning are related to immobility. Often these problems are interrelated. Nursing care must focus on all of these dimensions, not just on physical problems (Box 45-4).

Abrupt changes in cognition may have a physiological cause, such as surgery, a medication reaction, a pulmonary embolus, or an acute infection. For example, compromised older patients have confusion as their primary symptom when experiencing a pulmonary emboli or an acute urinary tract infection. Identifying confusion is an important component of the nurse's assessment. Acute confusion in older adults is not normal and should be thoroughly examined (RNAO, 2010b; Touhy et al., 2012).

Common reactions to immobilization are boredom, feelings of isolation, depression, and anger. Determine the patient's emotional background, including any history of anxiety or depression. Explore the patient's family and social network to identify those at greater risk for social isolation and their available resources. Observe for changes in a patient's emotional status. Examples of change that may indicate psychosocial concerns are a cooperative patient who becomes less cooperative or an independent patient who asks for more help than is

BOX 45-4 RESEARCH HIGHLIGHT

The Meaning of Mobility

Research Focus

It is widely known that decreased mobility contributes to physical and psychological impairment. Little is known, however, about the significance of mobility to other residents and to nurses in long-term care facilities. The purpose of this study was to determine nurses' and residents' perceptions of mobility in order to develop strategies that would support mobility in the institutionalized adult.

Research Abstract

In this exploratory, qualitative study by Bourret et al. (2002), residents and nursing staff made up focus groups in three long-term care facilities. A total of 20 residents and 15 nurses participated in the study. When asked about the importance of mobility, both groups identified it as key to quality of life. Older adults equated mobility with freedom, choice, and independence. Nurses valued mobility and associated it with freedom and autonomy. Both nurses and residents viewed having to wait for assistance as an impediment to mobility. Nurses identified further obstacles such as heavy workload and lack of time. Residents focused on physical barriers such as steep ramps, crowded elevators, and the negative attitudes of staff.

Evidence-Informed Practice

- Mobility is central to patients' quality of life and well-being.
- Nurses play a key role in assessing and assisting patients with their mobility needs.
- Nurses should focus on minimizing obstacles to mobility.
- Nurses should coordinate with other health care providers to meet patients' mobility needs.
- Nurses need to use creative strategies to encourage mobility in older adults.

Reference: Bourret, E., Bernick, L., Cott, C., & Kontos, P. (2002). The meaning of mobility for residents and staff in long-term care facilities. *Journal of Advanced Nursing*, 37(4), 338–345.

necessary. Try to determine the reasons for such alterations. Identify how the patient usually copes with loss (see Chapters 28 and 29). A change in mobility status, whether permanent or not, may cause a grief reaction. Families are a key resource for information about behaviour changes.

Unexplained changes in the sleep–wake cycle must be recognized and corrected. Most can be prevented or minimized, such as those occurring because of nursing activities, a noisy environment, or discomfort. They may also occur because of the effects of medications such as analgesics, sleeping pills, or cardiovascular drugs (see Chapter 40).

Whereas psychosocial changes usually occur gradually, observe the patient's behaviour on a daily basis. If behavioural changes occur, determine the causes and evaluate the changes as short or long term. Identification of the cause will help you to design appropriate nursing interventions. For example, a fear of falling often limits the bariatric or elderly patients' mobility; fear may be related to past experiences of falling and not being able to get up (RNAO, 2005a). Interventions include encouraging the patient to lean forward before standing rather than standing straight up, and teaching the patient how to get up and down from the floor, with assistance if needed.

Developmental Assessment. Assessment of the patient who is immobilized should include developmental

considerations to ensure that the patient's needs are identified. When caring for a young child, determine whether the child can meet developmental tasks and is progressing normally. The child's development may regress or be slowed because of immobilization. By identifying a child's overall developmental needs, you can design nursing therapies to maintain normal development. You may also need to assure the parents that developmental delays are usually temporary.

Immobilization of a family member changes the family's functioning. The family's response to this change may lead to problems, stress, and anxieties. Children seeing parents who are immobile may have difficulty understanding what is occurring and may have difficulty coping.

Immobility can have a significant effect on the older adult's levels of health, independence, and functional status. Nursing assessment will enable you to determine the older patient's ability to meet needs independently and to adapt to developmental changes such as declining physical functioning and altered family and peer relationships. A decline in developmental functioning needs prompt investigation to determine why the change occurred and what can be done to return the patient to an optimal level of functioning as soon as possible. Activities that reduce immobility and promote participation in ADLs are vital to prevent functional decline (Kawamoto et al., 2006). Assessment should also include the patient's home and community to identify factors that are risks to the patient's mobility and safety (see Chapter 36).

Patient Expectations

Patients may have unrealistic expectations of themselves or their caregivers. They may agree with the staff and understand their limitations, or they may set their expectations of themselves too high or too low. Some patients may expect to be waited on, and other patients may want to do as much as possible. Ask patients to explain what they know about their mobility status, what questions they and their families have, and how the immobility is affecting their goals.

❖Nursing Diagnosis

A patient who is partially or completely immobilized may have one or more nursing diagnoses. The two diagnoses most directly related to mobility problems are *impaired physical mobility* and *risk for disuse syndrome*. The diagnosis of *impaired physical mobility* is used for the patient who has some limitation but is not completely immobile. The diagnosis of *risk for disuse syndrome* should be considered for the patient who is immobile and at risk for multisystem pathophysiology because of inactivity. The list of potential diagnoses is extensive, because immobility affects multiple body systems:

- *Activity intolerance*
- *Ineffective airway clearance*
- *Ineffective breathing pattern*
- *Ineffective individual coping*
- *Risk for disuse syndrome*
- *Risk for fluid volume deficit*
- *Impaired gas exchange*
- *Risk for infection*
- *Risk for injury*
- *Impaired physical mobility*
- *Impaired skin integrity*
- *Risk for impaired skin integrity*
- *Disturbed sleep pattern*

BOX 45-5 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Measure range of motion (ROM) during exercises of extremities.	Patient has limited ROM with left shoulder. Patient has impaired coordination while attempting to perform ROM with left shoulder.	<i>Impaired physical mobility related to left shoulder pain.</i>
Observe patient use left shoulder in activities of daily living.	Patient is reluctant to attempt movement with left shoulder.	
Ask patient about perception of pain.	Patient complains of sharp pain in shoulder.	
Ask patient about endurance and activity tolerance.	Patient reports decreased muscle strength in left shoulder.	

- *Social isolation*
- *Ineffective (peripheral) tissue perfusion*
- *Impaired urinary elimination*

Through assessment you should find clusters of data indicating whether a patient is at risk or if an actual problem exists. Such clusters of data should include defining characteristics that support the diagnostic label and probable cause of the diagnosis. It is important to determine the probable cause of the diagnosis (on the basis of assessment data) in order to plan patient-centred goals and subsequent nursing interventions. For example, *impaired physical mobility related to bed rest* requires different interventions than those for *impaired physical mobility related to pain in the left shoulder*. Thus, you must identify and cluster defining characteristics that support the nursing diagnosis selected (Box 45-5).

Often, the physiological dimension is the major focus of nursing care for patients with impaired mobility, and the psychosocial and developmental dimensions are neglected. However, all dimensions are important to health. For example, during immobilization, social interaction and stimuli tend to be decreased. Ultimately, the patient may become isolated, withdrawn, and bored. Such patients may frequently use the call bell to request minor physical attention when their real need is greater socialization. Nursing diagnoses for health needs in developmental areas reflect changes from the patient's normal activities. Immobility can lead to a developmental crisis if the patient is unable to resolve problems and continue to mature.

Immobility may also lead to complications such as pulmonary emboli or pneumonia. If these conditions develop, you will need to collaborate with the physician or nurse practitioner for prescribed therapy to intervene.

Planning

During planning, you will need to synthesize information from resources such as knowledge of the roles of respiratory

Figure 45-10 Critical thinking model for immobility planning.

therapy, occupational therapy, and physiotherapy; professional standards such as the RNAO (2005a, 2005b, 2007) guidelines for prevention of falls and pressure ulcers; qualities involving creativity and perseverance; and past experience with similar patients (Figure 45-10).

Goals and Outcomes

Develop an individualized care plan for each nursing diagnosis (Box 45-6). You and the patient, including the family, should mutually develop goals and expectations for care. Goals are to be individualized, realistic, and measurable, focusing on prevention of problems or risks to body alignment and mobility.

The goals and expected outcomes are developed to assist the patient in achieving his or her highest level of mobility. In addition, these goals may be written to reduce the hazards of immobility. For example, a patient who has left-sided paralysis after a stroke may have two long-term goals. The first, directed toward improved mobility, may be "Patient uses walker to ambulate around the home and grocery store." A parallel goal, directed toward the hazards of immobility, may be "Patient's skin remains free of pressure." Both of these goals are essential to restoring maximum mobility for this patient. Because sensation is impaired, both the patient and caregivers must be aware of the patient's need to have the skin free of pressure. Expected outcomes for the second goal follow on p. 1215:

► BOX 45-6 NURSING CARE PLAN

Impaired Physical Mobility

Assessment

Ms. Barbara Adams, an 84-year-old patient, has been admitted for rehabilitation after a total hip replacement for osteoarthritis five days ago. The wound is clean, dry, and intact. Staples are to be removed in nine days. She is weight bearing as tolerated (WBAT). She is not able to safely transfer independently from a chair to the bed. She states that she is “afraid of falling” and frequently refuses to get out of bed. She rates her pain as a 2 on a scale of 0 to 10. Ms. Adams has a history of smoking. She states that she needs pain medication to help her sleep during the night but does not need any during the day.

Assessment Activities

Assess Ms. Adams’s pain level.

Findings and Defining Characteristics

She rates her pain as a 2 on a scale of 0 to 10. She states that she needs pain medication at night to help her sleep, but does not need any during the day.

Assess Ms. Adams’s ability to transfer.

She is not able to transfer without help from chair to bed.

Ask Ms. Adams how her surgery has affected her mobility.

She responds that she is “afraid of falling,” and she frequently refuses to get out of bed.

Assess Ms. Adams’s wound status.

Wound is clean, dry, and intact.

Nursing Diagnosis: Impaired physical mobility related to musculoskeletal impairment from surgery and a fear of falling.

Planning

Goals (Nursing Outcomes Classification)*

Ms. Adams will be free from skin breakdown by discharge.

Expected Outcomes

Tissue Integrity: Skin

Patient’s skin will remain intact.

Patient’s skin will be free of erythema.

Ms. Adams will exhibit no evidence of deep vein thrombosis (DVT) by discharge.

Tissue Perfusion: Peripheral

Patient’s calf diameters will remain within 1 cm of baseline through discharge.

Patient’s lower extremity pulses will remain equal.

Patient will have no complaints of calf pain.

Ms. Adams will be able to safely transfer with assistance within two days.

Mobility Level

Patient will transfer with assistance three times per day within two days.

Patient will state fear of falling during transfer is less within two days.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2007). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]

Circulatory Care

Administer low-dose heparin as ordered.

Rationale

Administration of low-dose heparin has been shown to reduce risk for vein thrombosis.

Apply graduated compression stockings as ordered and remove them each shift for hygiene.

Application increases venous tone, improving venous return and reducing venous stasis.

Reinforce antiembolic exercises while awake.

Exercises promote venous return.

Assist patient out of bed slowly.

Moving slowly will decrease the likelihood of orthostatic hypotension.

Moving the patient slowly will also avoid the perception by the patient of being rushed, which may cause the patient to become fearful.

► BOX 45-6 NURSING CARE PLAN—cont'd

Interventions (Nursing Interventions Classification)[†]

Skin Surveillance

Instruct patient to shift position every 1 to 1.5 hours while awake.

Rationale

Position changes should occur every 1 to 1.5 hours or more frequently if needed. This reduces the risk of pressure ulcer development.

When recumbent, place patient in 30-degree lateral position.

The 30-degree lateral position reduces pressure from the sacral area and reduces the risk of skin breakdown (RNAO, 2007).

Keep patient's heels off of bed by placing a pad under the lower legs.

Use of a thin pad under the lower legs raises the heels just enough so that a paper can slide between the heels and the bed, thereby reducing the pressure on the heels so that tissue blood flow is maintained (RNAO, 2005b).

Positioning

Explain positioning procedure to patient.

Reduces anxiety

Refer patient to physiotherapy for transfer training.

Helps to strengthen muscles used in transfer

Encourage patient to assist in transfer and positioning.

Promotes independence

Teach patient safe positioning after total hip replacement, for example, no hip flexion >90 degrees, do not cross legs, do not lie on affected side, and when in bed use a pillow between the knees.

Minimizes risk of dislocation of hip. Patient education is important for continued rehabilitation and healing

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Ask Ms. Adams if her mobility has improved postoperatively. Observe patient transfer from bed to chair.

Patient Response and Finding

Patient is able to transfer from the chair to the bed with assistance.

Achievement of Outcome

Patient has achieved goal of transferring with assistance.

Observe Ms. Adams's skin integrity at each shift.

Patient's wound remains clean, dry, and intact. No breakdown is noted on extremities.

Patient has achieved outcome that skin will remain intact.

Perform circulatory assessment of extremities at every shift.

Patient's calf diameters remain within 1 cm of baseline. Swelling, pain, redness, and warmth are not evident.

DVT is not evident.

Ask Ms. Adams to rate her fear of falling on a scale of 0 to 10.

Patient rates fear of falling a 7 on a scale of 0 to 10.

Outcome of decrease in fear of falling has not been totally achieved.

Patient is getting out of bed every shift.

Continue to encourage patient.

- Patient's skin colour and temperature return to normal baseline within 20 minutes of position change.
- Patient's skin remains dry and intact.

Setting Priorities

In developing a care plan, it is important to set priorities so that immediate needs are attended to first. This is particularly important when patients have multiple diagnoses (Figure 45-11). Plan therapies according to the severity of risks to the patient. Individualize the plan according to the patient's developmental stage, level of health, and lifestyle. The immediacy of any problem is determined by the effect the problem has on the patient's mental and physical health.

Potential complications should not be overlooked. Many times, actual problems such as pressure ulcers and disuse osteoporosis get addressed only after they develop. Therefore,

you must be vigilant in monitoring the patient, reinforcing prevention techniques to both the patient and other caregivers, and supervising unregulated care providers (UCPs) in carrying out activities aimed at preventing complications of impaired mobility.

Continuity of Care

The interventions planned for the patient may be done directly by the nurse or delegated to UCPs. UCPs can reinforce leg exercises, use of the incentive spirometer, and coughing and deep breathing (see Chapter 38). They may also turn and position patients, apply elastic stockings, and assess leg circumferences and height and weight.

Because many of the skills associated with care of the patient who is immobile can be delegated, you need to be vigilant in performing routine assessments to identify any

Figure 45-11 Concept map for patient with quadriplegia related to an acute spinal cord injury at C7.

developing complications early. It is also your responsibility to inform the UCP when patients are at risk for immobility hazards so that complications can be prevented. For example, although turning and positioning of a patient who is comatose may be delegated, you must ensure that it is done correctly and that the position is changed frequently enough to reduce the risk of poor alignment and future injury to the skin and musculoskeletal system. The frequency of turning is based on patient assessment for risk of pressure ulcer development (see Chapter 46).

Collaborate with other health team members such as physiotherapists or occupational therapists when considering a patient's mobility needs. For example, physiotherapists are a resource for planning ROM or strengthening exercises, and occupational therapists are a resource for planning ADLs that patients need to modify or relearn. Discharge planning begins when a patient enters the health care system. Consideration must be given to the patient's home environment when setting goals and planning therapies to maintain or improve body alignment and mobility. Referrals should be made early in the care process for ongoing care and therapy at home to help the patient remain mobile or further regain mobility at home.

❖ Implementation

Health Promotion

Health promotion activities are an essential part of primary health care and include a variety of interventions that can be divided into education, prevention, and early detection.

Encouragement of exercise should be a key health promotion strategy for all individuals, regardless of mobility issues (see Chapter 35). Engaging in regular exercise maintains the health of bones, muscles, and joints, thus promoting mobility.

Health promotion for the nurse includes additional areas of attention. Nurses must advocate for a healthy work environment for themselves and their patients. The availability of safe patient-handling equipment, the existence of transfer and lift policies, and staff education are just some of the key features of a healthy work environment (see Chapter 35).

Acute Care

In the acute care setting, use interventions to reduce the hazards of immobility. You should also know proper positioning and transferring techniques to safely move patients (see Chapter 35).

Immobility Hazards. Patients in acute care settings may demonstrate some problems associated with prolonged immobility, such as impaired respiratory status, orthostatic hypotension, and impaired skin integrity. For these patients, nursing interventions are designed to reduce the impact of immobility on body systems and prepare the patient for the restorative phase of care.

Metabolic System. Patients who are immobile often require a high-protein, high-calorie diet and possibly vitamin C and zinc supplements. Protein is needed to repair injured tissue and rebuild depleted protein stores. A high-calorie intake provides sufficient fuel to meet metabolic needs and to replace subcutaneous tissue. Supplementation with vitamin C

and zinc, if zinc stores are low, is needed for skin integrity and wound healing (see Chapter 46).

If the patient is unable to eat, nutrition must be provided parenterally or enterally. Enteral feedings include delivery through a nasogastric, gastrostomy, or jejunostomy tube of high-protein, high-calorie solutions with complete requirements of vitamins, minerals, and electrolytes (see Chapter 42). Total parenteral nutrition refers to delivery of nutritional supplements through a central or peripheral intravenous catheter.

Respiratory System. Nursing interventions for the respiratory system are aimed at promoting expansion of the chest and lungs, preventing stasis of pulmonary secretions, maintaining a patent airway, and promoting adequate exchange of respiratory gases.

Promoting Expansion of the Chest and Lungs. Changing the position of the patient at least every two hours allows the dependent lung regions to re-expand. Re-expansion maintains the elastic recoil property of the lungs and clears the dependent lung regions of pulmonary secretions.

Encourage the patient to deep breathe and cough every one to two hours. Alert patients can be taught to deep breathe or yawn every hour or to use an incentive spirometer (see Chapter 38). Instruct the patient to take in three deep breaths and cough with the third exhalation. This technique produces a more forceful, productive cough without excessive fatigue. These respiratory interventions will aid alveolar expansion and prevent atelectasis. Coughing reduces the stasis of pulmonary secretions.

If abdominal binders are required, they should be removed every two hours to allow the patient to breathe deeply. Binders must be assessed for correct positioning and adjusted as necessary to prevent interference with respirations. Often, patients will wear the binder only when ambulating. Specific physician instructions for the use of binders will vary.

Preventing Stasis of Pulmonary Secretions. Stagnant secretions accumulating in the bronchi and lungs may lead to growth of bacteria and subsequent development of pneumonia. Changing the patient's position every two hours can reduce stagnation of secretions. This change rotates the dependent lung, mobilizing secretions.

The patient who is immobile should take in a minimum of 2000 mL of fluid a day, if not contraindicated, to help keep mucociliary clearance normal. In patients free from infection and with adequate hydration, pulmonary secretions will appear thin, watery, and clear. The patient can easily remove the secretions by coughing. Without adequate hydration, the secretions are thick and difficult to remove. Encouragement of fluid intake also benefits bowel and urine elimination and aids in maintaining circulation and skin integrity.

Chest physiotherapy (CPT) (percussion and positioning) is an effective method for preventing pulmonary secretion stasis. CPT techniques help the patient to drain secretions from specific segments of the bronchi and lungs into the trachea so that the patient can cough and expel the secretions. Respiratory assessment findings can be used to identify areas of the lungs requiring CPT (see Chapter 38).

Maintaining a Patent Airway. Patients who are immobilized are generally weakened. If weakness progresses, the cough reflex gradually becomes inefficient. The stasis of secretions in the lungs may be life-threatening because hypostatic pneumonia can easily develop. The dislodging and mobilizing of the stagnant secretions reduce the risk of pneumonia. Assessment findings that indicate this condition include

productive cough with greenish-yellow sputum; fever; pain on breathing; crackles and wheezes; and dyspnea. You should actively work with the patient to deep breathe and cough every one to two hours as described earlier, in the section "Promoting Expansion of the Chest and Lungs."

In the patient who is immobilized, an obstructed airway is usually the result of a mucous plug. You can implement several therapies (e.g., CPT) to reduce the risk of mucous plugs and to maintain a patent airway. Nasotracheal or orotracheal suction techniques may be used to remove secretions in the upper airways of a patient who is unable to cough productively. This procedure must be performed aseptically. You can also suction secretions when patients have artificial airways such as an endotracheal or tracheal tube. Insert a catheter into the artificial airway using sterile technique. This can be used to remove pulmonary secretions from the upper and lower airways (see Chapter 38).

Cardiovascular System. The effects of bed rest or immobilization on the cardiovascular system include orthostatic hypotension, increased cardiac workload, and thrombus formation. Nursing therapies are designed to minimize or prevent these alterations.

Reducing Orthostatic Hypotension. After bed rest, patients usually have increased pulse rate and decreased pulse pressure and blood pressure. A large decrease in blood pressure when rising to a sitting or standing position (orthostatic hypotension) can result in lightheadedness and fainting (Copstead-Kirkhorn & Banasik, 2011). When getting a patient up for the first time, you should be assisted by at least one other person. This is a precautionary step in case the patient faints.

Interventions should be directed toward reducing or eliminating the effects of orthostatic hypotension. Attempt to get the patient moving as soon as the physical condition allows, even if this only involves sitting at the side of the bed (dangling) or moving to a chair. Changing position slowly and gradually helps to prevent orthostatic hypotension. Before the patient gets up from the bed, slowly raise the head of the bed so that the patient is sitting up for about 10 minutes before standing. Then, help the patient to sit on the side of the bed for a few minutes before the patient stands up. This activity helps maintain muscle tone and increase venous return. Then help the patient to stand. It is important to ask the patient if he or she feels weak or dizzy or sees spots before the eyes. If any of these symptoms occur, help the patient sit down again.

Reducing Cardiac Workload. Cardiac workload is increased by immobility. A primary intervention is to discourage patients from holding their breath while bearing down (the Valsalva manoeuvre), as may occur when the patient is moving up in bed or straining to defecate. The Valsalva manoeuvre increases intrathoracic pressure, thus decreasing venous return and cardiac output. When the strain is released, venous return and cardiac output immediately increase and systolic blood pressure and pulse pressure rise. These pressure changes produce a reflex bradycardia and a possible decrease in blood pressure that may cause sudden cardiac death in patients with heart disease. Remind the patient to breathe out while moving or being lifted up in bed.

Preventing Thrombus Formation. The most cost-effective way to address the problem of deep vein thrombosis (DVT) is through prevention (prophylaxis). It begins with identifying patients at risk and continues throughout the time patients are immobile or otherwise at risk. This is clearly a collaboration between nurses and physicians. You can easily identify risk

factors during an admission nursing assessment. Many interventions reduce the risk of thrombus formation in the patients who are immobilized. Leg exercises, encouragement of fluids, position changes, and teaching of such preventive measures should begin when the patient becomes immobile. Preoperative patients should be given this information before surgery (see Chapter 48). Other interventions such as intermittent pneumatic compression (IPC) and sequential compression devices (SCDs) require a physician's order. Maintenance and administration of prophylaxis is a nursing role, and nurses can determine when the patient is fully mobile postoperatively, decreasing the continued risk for DVT.

Medications also require a physician's order. Subcutaneous heparin and low-molecular-weight heparin (LMWH), such as tinzaparin, enoxaparin, and dalteparin, are the most widely used drugs in the prophylaxis of DVT. The recent approval of rivaroxaban and dabigatran, in addition to the long-standing availability of warfarin, means more oral options for DVT prophylaxis and anticoagulation therapy. Heparin is considered the gold standard for treatment because it has been well studied and validated. Common dosage for heparin therapy is 5000 units given subcutaneously every 12 hours until the patient is fully mobile or discharged (Geerts et al., 2008). Anticoagulants suppress clot formation and thus you must continually assess the patient for signs of bleeding, such as increased bruising, guaiac-positive stools, and bleeding gums. Although most patients receiving prophylactic doses of anticoagulants do not experience side effects, the risk of bleeding is present.

SCDs and IPCs consist of sleeves or stockings made of fabric or plastic that are wrapped around the leg and secured with Velcro (Box 45-7). The sleeves are then connected to a pump that alternately inflates and deflates the stocking around the leg. A typical cycle is inflation for 10 to 15 seconds and deflation for 45 to 60 seconds. Inflation pressures average 40 mm Hg. Use of SCDs or IPCs on the legs decreases venous stasis by increasing venous return through the deep veins of the legs. For optimal results, use of SCDs or IPCs is begun as soon as possible and maintained until the patient becomes fully ambulatory. Graduated compression stockings can help prevent DVT, but patients must receive the right size, and the SCD or IPC must be used correctly.

Elastic stockings (sometimes called *thromboembolic device [TED] hose* or thigh-high antiembolic stockings) also aid in maintaining external pressure on the muscles of the lower extremities and thus may promote venous return (Box 45-8). When considering applying elastic stockings, first assess the patient's suitability for wearing them. The stockings should not be applied if any local condition affects the leg (e.g., any skin lesion, gangrenous condition, or recent vein ligation) because application may compromise circulation. You will need to measure the patient's legs with a tape measure to determine proper stocking size. The stockings must be applied properly, and they must be removed and reapplied at least once per shift. Assess circulation at the toes to ensure that the hose are not too tight. In addition, the stockings should always be clean and dry; it may be useful for the patient to have two pairs.

Positioning techniques aid in reducing compression of the leg veins. Proper positioning used with other therapies (e.g., heparin or elastic stockings) aids in reducing the patient's risk of thrombus formation. When positioning patients, use caution to prevent pressure on the posterior knee and deep veins in the lower extremities. Patient teaching should include avoiding

► BOX 45-7 Procedural Guideline

Application of Sequential Compression Stockings

Delegation Considerations:

The skill of applying sequential compression stockings (SCSs) can be delegated to unregulated care providers (UCPs). The nurse is responsible for assessing circulation in the extremities; therefore, when application of the SCSs is delegated, it is important to instruct the UCP to do the following:

- Notify the nurse if the patient complains of pain in the leg.
- Notify the nurse if discoloration develops in the extremities.

Equipment:

Tape measure, sequential compression stockings, stockinette, hygiene supplies

Procedure:

1. Assess the patient for the need for sequential compression stockings.
2. Obtain baseline assessment data about the status of circulation, pulse, and skin integrity on the patient's lower extremities before initiating application of sequential compression stockings.
3. Measure the patient for proper-size stocking by measuring around the largest part of the patient's thigh. Review the manufacturer's directions regarding measuring for proper fit.
4. Perform hand hygiene. Provide hygiene to lower extremities if needed.
5. Place a protective stockinette over the patient's leg.
6. Wrap the stocking around the leg, starting at the ankle, with the opening over the patella (see Step 6 illustration).
 - A. Attach the stockings to the insufflator and verify that the intermittent pressure is between 35 and 45 mm Hg.

Step 6 Application of sequential compression stocking.

7. Record date and time of stocking application, and stocking length and size in nurses' notes.
8. Record condition of skin and circulatory assessment.
9. Monitor skin integrity and circulation to the patient's lower extremities as ordered or according to the manufacturer's guidelines.

crossing the legs, not sitting for prolonged periods of time, not wearing clothing that constricts the legs or waist, not putting pillows under the knees, and avoiding massaging the legs.

Although ROM exercises are designed to reduce the risk of contractures, they may also aid in preventing thrombi. Activity causes contraction of the skeletal muscles, which in turn exerts pressure on the veins to promote venous return, thereby reducing venous stasis. Specific exercises that help prevent thrombophlebitis are ankle pumps, foot circles, and knee flexion.

► BOX 45-8 Procedural Guideline

Application of Elastic Stockings

Delegation Considerations:

The skill of applying elastic stockings can be performed by unregulated care providers (UCPs). The nurse is responsible for assessing circulation to the lower extremities; therefore, when application of the stockings is delegated, it is important to instruct the UCP to report if the patient develops leg pain or discoloration.

Equipment:

Tape measure, elastic stockings, hygiene supplies

Procedure:

1. Assess the need for elastic stockings and condition of the patient's skin.
2. Observe for conditions that might contraindicate use of stockings.
3. Perform hand hygiene. Provide hygiene to lower extremities if needed.
4. Use tape measure to measure the patient's legs to determine proper stocking size (measure according to manufacturer's directions). Elastic stockings come in two lengths: knee length and thigh length.
5. Apply stockings:
 - A. Turn elastic stocking inside out up to the heel. Place one hand into the sock, holding heel. Pull top of sock with the other hand inside out over foot of sock.
 - B. Place patient's toes into the foot of the elastic stocking, making sure that sock is smooth (see Step 5B illustration).

Step 5B

- C. Slide remaining portion of sock over the patient's foot, being sure that the toes are covered. Make sure the foot fits into the toe and heel position of the sock (see Step 5C illustration).

Step 5C

- D. Slide top of sock up over patient's calf until sock is completely extended. Be sure sock is smooth and no ridges or wrinkles are present, particularly behind the knee (see Step 5D illustration).

Step 5D

6. Instruct patient not to roll socks partially down.
7. Record date and time of stocking application, and stocking length and size in nurses' notes.
8. Record condition of skin and circulatory assessment.

Ankle pumps, sometimes called *calf pumps*, include alternating plantar flexion and dorsiflexion. To perform foot circles, the patient rotates the ankle. Making the letters of the alphabet with their feet every one to two hours is a good exercise for patients. Knee flexion involves alternately extending and flexing the knee. These exercises are sometimes referred to as antiembolic exercises and should be done hourly while the patient is awake.

When DVT is suspected, you should report it immediately. The leg should be elevated with no pressure on the thrombus. The family, patient, and all health care personnel should be instructed to not massage the area because of the danger of dislodging the thrombus.

Musculoskeletal System. The patient who is immobilized must receive some exercise to prevent or minimize muscle atrophy and joint contractures. If the patient is unable to move part or all of the body, perform passive ROM exercises for all immobilized joints while bathing the patient and at least two or three more times a day (see "Restorative Care" section). If one extremity is paralyzed, the patient can be taught to put each joint independently through its ROM. Patients on bed rest should have active ROM exercises incorporated into their daily

schedules. Nurses can teach patients to integrate exercises during ADLs. Some orthopedic conditions require frequent passive ROM exercises to restore the injured joint's function after surgery. Patients with such conditions may use automatic equipment (continuous passive motion [CPM]) for passive ROM exercises (Figure 45-12). The CPM machine moves an extremity to a prescribed angle for a prescribed period. This is beneficial when the patient must gradually increase the degree and duration of flexion and extension. Researchers are currently investigating new uses for CPM. In one study, patients who had suffered a cerebrovascular accident (CVA) and who received CPM therapy to their affected shoulder had better joint stability than that of patients who received traditional ROM exercises (Lynch et al., 2005).

Active ROM exercises help maintain function of the musculoskeletal system. You should also plan interventions for the gradual return of mobility for patients who will be able to resume normal activity. The best nursing intervention is establishing an individualized progressive exercise program (Shin et al., 2006). A progressive exercise program gradually increases the patient's physical activity to reverse the deconditioning associated with immobility.

Figure 45-12 Continuous passive motion machine.

Encouraging the use of isometric-type exercises will also help the patient maintain the musculoskeletal system during acute care. Review the patient's chart and collaborate with the physician to alert you to any possible contraindications before initiating isometric exercises. An isometric exercise program is designed for the specific needs of a patient. For example, to prepare the patient for walking with crutches, you may implement an exercise program that includes isometric exercises targeting the biceps and triceps. Tell the patient to stop the activity if pain, fatigue, or discomfort are experienced, and reinforce this as necessary.

Generally, in an isometric exercise the muscle group is tightened (contracted) for 10 seconds and then completely relaxed for several seconds. Repetitions are gradually increased for each muscle group until the isometric exercise can be repeated 8 to 10 times. Instruct patients to perform the exercises slowly and to increase repetitions as their physical condition improves. Muscle groups used for walking (quadriceps and gluteal) should be exercised isometrically four times per day until the patient is ambulatory (Hoeman, 2008).

Teaching, referral, and interdisciplinary collaboration are important for patients with limited mobility. Depending on the setting and resources available, you may want to refer the patient to a physiotherapist or kinesiologist. The therapist would set up the specific exercise program, and the nurse would reinforce it.

Elimination System. The nursing interventions for maintaining optimal urinary functioning are directed at keeping the patient well hydrated and preventing urinary stasis, calculi, and infections without causing bladder distension.

Adequate hydration (i.e., 2000 to 3000 mL of fluids per day) helps prevent renal calculi and urinary tract infections. The patient who is well hydrated should void large amounts of dilute urine that are approximately equal to fluid intake. If the patient is incontinent, modify the care plan to include toileting aids and a hygiene schedule so that the increased urinary output does not cause skin breakdown.

To prevent bladder distension, assess the frequency and amount of urinary output. A patient who continually dribbles urine and whose bladder is distended may have overflow incontinence. If the patient does not have voluntary control of bladder elimination, bladder training may be necessary. If the patient experiences bladder distension, you may be required to insert a straight catheter or an indwelling Foley catheter (see Chapter 43).

The frequency and consistency of bowel movements must be recorded. A diet rich in fluids, fruits, vegetables, and fibre can facilitate normal peristalsis. If a patient is unable to maintain regular bowel patterns, stool softeners, cathartics, or enemas may be needed (see Chapter 44).

Integumentary System. The major risk to the skin from restricted mobility is the formation of pressure ulcers. Preventing a pressure ulcer is much less expensive than treating one, and thus preventive nursing interventions are imperative as outlined in the RNAO (2005b) Best Practice Guideline: *Risk Assessment and Prevention of Pressure Ulcers* (see Chapter 46).

Interventions aimed at prevention are positioning, skin care, and the use of therapeutic devices to relieve pressure. The patient who has impaired mobility should be assisted or encouraged to change position according to the patient's activity level, perceptual ability, treatment protocols, and daily routines. Although turning every one to two hours is recommended for preventing ulcers, it may also be necessary to use devices for relieving pressure. The amount of time that a patient sits uninterrupted in a chair should be limited to one hour or less, although this time interval is individualized. The patient should be repositioned frequently because uninterrupted pressure will cause skin breakdown. You should teach patients who are able to do so to shift their weight every 15 minutes. Patients who are chair-bound should have a device for the chair that reduces pressure; however, doughnut-shaped devices should not be used (RNAO, 2007). If a pressure ulcer does develop, treatment should commence immediately based on RNAO's (2007) Best Practice Guideline: *Assessment and Management of Stage I–IV Pressure Ulcers* (see Chapter 46).

Psychosocial Changes. Through assessment, you can identify effects of prolonged immobilization on the patient's psychosocial dimension. People who have a tendency toward depression or mood swings are at greater risk for developing psychosocial changes during bed rest or immobilization.

You should anticipate changes in the patient's psychosocial status and provide routine and informal socialization. Nursing activities can be planned so that the patient can talk and interact with staff. If possible, the patient should be placed in a room with others who are mobile and interactive. If a private room is required, staff members and family should be asked to visit throughout the shift to provide meaningful interaction.

Provide stimuli to maintain a patient's orientation. Maintaining a calendar and clock; providing a newspaper, books, radio, or television; and encouraging visits from significant others may reduce the risk of social isolation and delirium (RNAO, 2010a). Spending time in the room talking and listening to the patient also helps reduce isolation.

An important part of nursing care for patients with mobility issues is encouraging them to perform as many ADLs as independently as possible. Patients should continue to perform personal grooming if they did so before their mobility was restricted. This type of activity preserves the patient's dignity and gives the patient a sense of accomplishment.

In institutional health care settings, nursing care given between 2200 hours and 0700 hours should be scheduled to minimize interruptions of sleep. For example, the nurse may administer medications and assess vital signs at the time when the patient is turned or receives special skin care.

Observe the patient's ability to cope with restricted mobility. If the nursing care plan is not improving coping patterns, a clinical nurse specialist, counsellor, social worker, spiritual

advisor, or other consultant may be needed. Their recommendations should be incorporated into the care plan.

Developmental Changes in Children. Ideally, patients with mobility challenges continue normal development; nursing interventions can help with this. Nursing care should provide mental and physical stimulation, particularly for a young child. Play activities can be incorporated into the care plan. Completing puzzles, for example, helps a child to develop fine motor skills, and reading helps the child to develop cognitively. Parents should be encouraged to stay with a child who is hospitalized. An immobilized child should be placed with children of the same age who are not immobilized, unless a contagious disease is present. You must watch for significant changes from normal behavioural patterns. If these changes continue, consult with a clinical nurse specialist, counsellor, or other health care provider who specializes in children.

Positioning Devices and Techniques. Patients with impaired function of the nervous, skeletal, or muscular system and with general weakness often require help to attain proper body alignment while in bed or sitting. You must assess skin integrity regularly for pressure points or skin breakdown when using positioning devices.

Several positioning devices are available for maintaining good body alignment for patients:

- **Pillows:** These provide support, elevate body parts, and can splint incisional areas, reducing postoperative pain during activity or coughing and deep breathing. Before using a pillow, you should determine whether it is the proper size. A thick pillow under the patient's head increases cervical flexion. A thin pillow under body prominences may be inadequate to protect skin and tissue from damage caused by pressure. When additional pillows are unavailable, or if they are an improper size, folded sheets, blankets, or towels can be used as positioning aids.
- **Wedge (or abductor) pillow:** This is a triangular-shaped pillow made of heavy foam used to maintain the legs in abduction after total hip replacement surgery.
- **Foot boot:** This maintains feet in dorsiflexion. Foot boots are made of rigid plastic or heavy foam (Figure 45-13). They keep the foot flexed at the proper angle and the weight of the bedsheets off the toes. Remove the foot boots two or three times a day to assess skin integrity and joint mobility.
- **Trochanter roll:** This prevents external rotation of the hips when the patient is in a supine position. A **trochanter roll**

is formed by folding a cotton bath blanket lengthwise to a width that will extend from the greater trochanter of the femur to the lower border of the popliteal space (Figure 45-14). The blanket is placed under the buttocks and then rolled counterclockwise until the thigh is in neutral position or in inward rotation. When correct alignment of the hip is achieved, the patella faces directly upward.

- **Sandbags:** These are sand-filled plastic tubes or bags that can be shaped to body contours. Sandbags can be used in place of or in addition to trochanter rolls. They immobilize an extremity or maintain body alignment.
- **Hand rolls:** These rolls maintain the thumb in slight adduction and in opposition to the fingers. A hand roll maintains the hand, thumb, and fingers in a functional position, thus preventing contractures (Figure 45-15). Evaluate the hand roll to make sure that the hand is indeed in a functional position. Hand rolls are most often used for patients whose arms are paralyzed or who are unconscious. Rolled washcloths should not be used as hand rolls, because they do not keep the thumb well abducted, especially in patients who have a spastic paralysis.
- **Hand-wrist splints:** These are individually moulded for the patient to maintain proper alignment of the thumb (slight adduction) and the wrist (slight extension). These splints should be used only by the patient for whom the splint was made (Figure 45-16).

Figure 45-14 Trochanter roll.

Figure 45-13 Foot boot.

Figure 45-15 Hand roll. Source: Courtesy J. T. Posey, Arcadia, CA.

Figure 45-16 Hand-wrist splint. **Source:** Sorrentino, S. A., Wilk, M. J., & Newmaster, R. (2009). *Mosby's Canadian textbook for the support worker* (2nd ed., p. 431, Fig 24-8). Toronto: Elsevier.

Figure 45-17 Patient using a trapeze bar.

- **Trapeze bar:** This is a triangular device that descends from a securely fastened overhead bar attached to the bed frame. A **trapeze bar** allows the patient to use his or her upper extremities to raise the trunk off the bed, to assist in transfer from bed to wheelchair, or to perform arm exercises (Figure 45-17). It is a useful device for helping to increase independence, maintain upper body strength, and decrease the shearing action from sliding across or up and down in bed.

Although procedures for each position have specific guidelines, some universal steps should be followed for patients who require positioning assistance (Skill 45-1). By following the guidelines, you reduce the risk of injury to the musculoskeletal system. When joints are unsupported, their alignment is impaired. Joints must be positioned in a slightly flexed position or their mobility is decreased. During positioning, it is important to also assess bony prominences (pressure points; see Figure 46-2). When actual or potential pressure areas exist, nursing interventions involve removal of the pressure, thus

decreasing the risk for development of pressure ulcers and further trauma to the musculoskeletal system. For patients at risk for pressure ulcers, the 30-degree lateral position should be used (see Chapter 46).

Supported Fowler's Position. In the supported Fowler's position, the head of the bed is elevated 45 to 60 degrees and the patient's knees are slightly elevated without pressure; the patient is sitting up in bed. Do not elevate the head of the bed more than 60 degrees because this would increase shearing force on the patient's back and heels (see Chapter 46). The angle of head and knee elevation and the length of time that the patient should remain in the supported Fowler's position vary depending on the patient's illness and overall condition. Supports must permit flexion of the hips and knees and proper alignment of the normal curves in the cervical, thoracic, and lumbar vertebrae. The following are common trouble areas for the patient in the supported Fowler's position (see Skill 45-1 for preventive measures):

- Excessive cervical flexion because the pillow at the head is too thick and the head thrusts forward
- Hyperextension of the knees, allowing the patient to slide to the foot of the bed
- Pressure on the posterior aspect of the knees, decreasing circulation to the feet
- External rotation of the hips
- Arms hanging unsupported at the patient's sides
- Unsupported feet or pressure on the heels
- Unprotected pressure points at the sacrum and heels

Supine Position. The supine position is a back-lying position. In the supine position, the relationship of body parts is essentially the same as in good standing alignment except that the body is in the horizontal plane. Pillows, trochanter rolls, and hand rolls or arm splints are used to increase comfort and reduce injury to the skin or musculoskeletal system. The mattress should be firm enough to support the cervical, thoracic, and lumbar vertebrae. Shoulders are supported, and the elbows are slightly flexed to control shoulder rotation. A foot support is used to prevent footdrop and maintain proper alignment. The following are some common trouble areas for patients in the supine position (see Skill 45-1 for preventive measures):

- Excessive cervical flexion because the pillow at the head is too thick and the head thrusts forward
- Head flat on the mattress
- Shoulders unsupported and internally rotated
- Elbows extended
- Thumb not in opposition to the fingers
- Hips externally rotated
- Unsupported feet
- Unprotected pressure points at the occipital region of the head, vertebrae, coccyx, elbows, and heels

Prone Position. The patient in the prone position is lying chest down. Often the head is turned to the side. If a pillow is under the head, it should be thin enough to prevent cervical flexion or extension and maintain alignment of the lumbar spine. Placing a pillow under the lower leg permits dorsiflexion of the ankles and some knee flexion, which promotes relaxation. If a pillow is unavailable, the ankles should be in dorsiflexion over the end of the mattress. Although the prone position is seldom used in practice, nurses should consider this as an alternative, especially in patients who normally sleep in this position. The prone position may also have some

Text continued on p. 1230

► SKILL 45-1 Moving and Positioning Patients in Bed

Delegation Considerations

The skills of moving and positioning patients in bed can be delegated to unregulated care providers (UCPs). The nurse is responsible for assessing the patient's level of comfort and for any potential hazards. It is important to instruct the UCP on any limitations affecting movement and positioning of the patient in bed.

Procedure

STEPS

1. Assess patient's body alignment and comfort level while patient is lying down.
2. Assess for risk factors that may contribute to complications of immobility:
 - A. Paralysis: Hemiparesis resulting from cerebrovascular accident; decreased sensation
 - B. Impaired mobility: Traction or arthritis or other contributing disease processes
 - C. Impaired circulation
 - D. Age: Very young, older adults
- E. Level of consciousness and mental status
- F. Assess condition of patient's skin.
3. Assess patient's physical ability to help with moving and positioning:
 - A. Age
 - B. Level of consciousness and mental status
 - C. Disease process
 - D. Strength, coordination
 - E. ROM
4. Assess physician's orders. Clarify whether any positions are contraindicated because of the patient's condition (e.g., spinal cord injury; respiratory difficulties; certain neurological conditions; presence of incisions, drain, or tubing).
5. Perform hand hygiene.
6. Assess for the presence of tubes, incisions, and equipment (e.g., traction).
7. Assess the ability and motivation of the patient, family members, and primary caregiver to participate in moving and positioning the patient in bed in anticipation of discharge to home.
8. Raise level of bed to a comfortable working height, and get extra help if needed.
9. Perform hand hygiene.
10. Explain procedure to patient.
11. Position patient flat in bed if this is tolerated.

Equipment

- Pillows
- Drawsheet or friction-reducing device
- Positioning devices as required (e.g., trochanter roll, extra pillows, hand rolls)

RATIONALE

- Provides baseline data for later comparisons. Determines ways to improve position and alignment.
- Increased risk factors require patient to be repositioned more frequently.
- Paralysis impairs movement and causes muscle tone changes; sensation can be affected. Because of difficulty in moving and poor awareness of the involved body part, the patient is unable to protect and position the affected body part.
- Traction or arthritic changes of affected extremity result in decreased range of motion (ROM).
- Decreased circulation predisposes the patient to pressure sores.
- Premature and young infants require frequent turning because their skin is fragile. Normal physiological changes associated with aging predispose older adults to greater risks for developing complications of immobility.
- Patients who are comatose or semicomatose are unable to convey areas of skin pressure, increasing the risk for skin breakdown.
- Provides a baseline to determine effects of positioning.
- Enables nurse to use patient's mobility and strength. Determines need for additional help. Ensures patient's and nurse's safety.
- Older adult patients may move more slowly and with less strength.
- Determines need for special aids or devices.
- Patients with altered levels of consciousness may not understand instructions and may be unable to help.
- Cardiopulmonary disease may require the patient to have the head of the bed elevated.
- Determines amount of assistance provided by patient during position change.
- Limited ROM may contraindicate certain positions.
- Placing patient in an inappropriate position could cause injury.
- Reduces transfer of microorganisms.
- Will alter positioning procedure and may affect patient's ability to independently change positions.
- Determines ability of the patient and caregivers to assist with positioning.
- Raises level of work to centre of gravity and provides for patient's and nurse's safety.
- Reduces transfer of microorganisms.
- Decreases anxiety and increases patient cooperation.
- Repositioning from a flat position decreases friction and possible shear on patient's skin.

Critical Decision Point: Before flattening the bed, account for all tubing, drains, and equipment to prevent dislodgement or tipping if caught in the mattress or bed frame as bed is lowered.

Continued

► SKILL 45-1 Moving and Positioning Patients in Bed-cont'd

12. Position patient in bed.

A. Assist patient in moving up in bed (one or two nurses). Note: Only a young child or a small patient requiring minimal assistance can be safely moved by one nurse.

(1) Remove pillow from under the head and shoulders, and place pillow at head of bed. Ask patient to cross arms across the chest.

(2) Face head of bed.

(a) Each nurse should have one arm under the patient's shoulders and one arm under the patient's thighs.

(b) Alternative position: Position one nurse at the patient's upper body. The nurse's arm nearest head of bed should be under the patient's head and opposite shoulder; the other arm should be under the patient's closest arm and shoulder. Position the other nurse at patient's lower torso. The nurse's arms should be under the patient's lower back and torso.

(3) Place feet apart, with foot nearest head of bed behind the other foot (forward-backward stance; see Step 12A(3) illustration).

Step 12A(3) Position of feet: feet placed apart in a forward-to-backward stance.

(4) Ask patient to flex knees with feet flat on bed.

(5) Instruct patient to flex neck, tilting chin toward chest.

(6) Instruct patient to assist moving by pushing with feet on bed surface.

(7) Flex knees and hips, bringing forearms closer to the level of the bed.

(8) Instruct patient to push with heels and elevate trunk while breathing out, thus moving toward head of bed on a count of 3.

(9) On count of 3, rock and shift weight from back to front leg. At the same time, the patient pushes with heels and elevates trunk.

B. Move patient up in bed with drawsheet or friction-reducing device (two nurses are needed).

(1) Adjust bed to appropriate height for caregiver's body mechanics. Place drawsheet or friction-reducing device under the patient by turning side to side. Have sheet extend from shoulders to thighs. Return patient to supine position.

(2) Position one nurse at each side of the patient.

(3) Grasp drawsheet or friction-reducing device firmly near the patient with palms facing up.

- Prevents striking of patient's head against head of the bed.
- Reduces surface area and friction.

- Facing the direction of movement prevents twisting of nurse's body while moving the patient.

- Prevents trauma to patient's musculoskeletal system by supporting shoulder and hip joints and evenly distributing weight.

- A wide base of support increases balance. This stance enables you to shift body weight as the patient is moved up in bed, thereby reducing force needed to move load.

- Decreases friction and enables patient to use leg muscles during movement.
- Prevents hyperextension of neck when moving patient up in bed.
- Reduces friction. Increases patient mobility. Decreases workload.
- Increases balance and strength by bringing the centre of gravity closer to the patient. Uses thighs instead of back muscles.
- Prepares patient for move. Reinforces assistance in moving up in bed. Increases patient cooperation. Breathing out avoids Valsalva manoeuvre.
- Rocking enables you to improve balance and overcome inertia. Shifting weight counteracts the patient's weight and reduces the force needed to move load. The patient's assistance reduces friction and workload.

- Supports patient's body weight and reduces friction during movement. Reduces risk of injury to caregivers and maximizes leverage to move the patient safely.

- Distributes weight equally between nurses.

► SKILL 45-1 Moving and Positioning Patients in Bed—cont'd

- (4) Place feet apart with forward-backward stance. Flex knees and hips. Shift weight from back to front leg, and move patient and drawsheet or friction-reducing device to desired position in bed.
 - (5) Realign patient in correct body alignment.
- C. Position patient in supported Fowler's position (see Step 12C illustration).

Step 12C Supported Fowler's position.

- (1) Elevate head of bed 45 to 60 degrees.
 - (2) Rest patient's head against mattress or on a small pillow.
 - (3) Use pillows to support arms and hands if the patient does not have voluntary control or use of hands and arms.
 - (4) Position pillow at lower back.
 - (5) Place a small pillow under thigh.
 - (6) Position patient's heel in heel boots or other heel pressure relief devices.
- Facing the direction of movement ensures proper balance. Shifting weight reduces the force needed to move load. Flexing knees lowers the centre of gravity and uses thighs instead of back muscles.
 - Prevents injury to musculoskeletal system.
 - Increases comfort, improves ventilation, and increases patient's opportunity to socialize or relax.
 - Prevents flexion contractures of cervical vertebrae.
 - Prevents shoulder subluxation from effect of downward pull of unsupported arms, promotes circulation by preventing venous pooling, and prevents flexion contractures of arms and wrists.
 - Supports lumbar vertebrae and decreases flexion of vertebrae.
 - Prevents hyperextension of knee and occlusion of popliteal artery caused by pressure from body weight.
 - Heel pressure relief devices are more effective than pillows for consistently reducing pressure from the mattress on the heels. When pillows are used, they must be repositioned each time the patient moves.

Critical Decision Point: A foot cradle may also be used in patients with poor peripheral circulation as a means of reducing pressure on the tips of a patient's toes.

D. Position patient with hemiplegia in supported Fowler's position.

- (1) Elevate head of bed 45 to 60 degrees.
 - (2) Position patient in sitting position as straight as possible.
 - (3) Position head on a small pillow with the chin slightly forward. If patient is totally unable to control head movement, hyperextension of the neck must be avoided.
- Increases comfort, improves ventilation, and increases patient's opportunity to relax.
 - Counteracts tendency to slump toward affected side. Improves ventilation and cardiac output, and decreases intracranial pressure. Improves patient's ability to swallow and helps to prevent aspiration of food, liquids, and gastric secretions.
 - Prevents hyperextension of neck. Too many pillows under the head may cause or worsen neck flexion contracture.

Critical Decision Point: If the patient has a paralyzed extremity, provide support for involved arm and hand on overbed table in front of patient. Place arm away from the patient's side and support elbow with pillow.

- Position *flaccid* hand in a normal resting position with the wrist slightly extended, arches of hand maintained, and fingers partially flexed. You may use a hand grip or section of rubber ball cut in half; clasp patient's hands together.
 - Position *spastic* hand with wrist in neutral position or slightly extended; fingers should be extended with palm down. It may be difficult to position spastic hands without the use of specially made splints for the patient (discuss with occupational therapist).
 - (4) Flex patient's knees and hips by using a pillow or folded blanket under the knees.
 - (5) Support feet in dorsiflexion with firm pillow or therapeutic boots or splints.
 - Ensures proper alignment. Flexion prevents prolonged hyperextension, which could impair joint mobility.
 - Prevents footdrop. Stimulation of ball of the foot by a hard surface has a tendency to increase muscle tone in a patient with extensor spasticity of lower extremity. Therapeutic boots or splints are manufactured with thick padding to cushion the heel and prevent pressure ulcers.
- E. Position patient in supine position.
- (1) Be sure patient is comfortable on back with head of bed flat.
 - Some patients' physical conditions will not tolerate a supine position.

Continued

► SKILL 45-1 Moving and Positioning Patients in Bed—cont'd

video

- (2) Place a small rolled towel under the lumbar area of the back.
 - (3) Place a pillow under upper shoulders, neck, or head.
 - (4) Place trochanter rolls or sandbags parallel to lateral surface of the patient's thighs.
 - (5) Place a small pillow or roll under ankle to elevate heels (see Step 12C illustration).
 - (6) Place firm pillows against bottom of patient's feet.
 - (7) Place foot boots on patient's feet, if necessary.
 - (8) Place pillows under pronated forearms, keeping upper arms parallel to patient's body (see Step 12E(8) illustrations).
- Provides support for lumbar spine.
 - Maintains correct alignment and prevents flexion contractures of cervical vertebrae.
 - Reduces external rotation of hip.
 - Reduces pressure on heels, helping to prevent pressure sores.
 - Maintains dorsiflexion and prevents footdrop.
 - Maintains feet in dorsiflexion. Prevents footdrop.
 - Reduces internal rotation of shoulder and prevents extension of elbows. Maintains correct body alignment.

Step 12E(8) Supine position with pillows in place.

- (9) Place hand rolls in patient's hands. Consider occupational therapy referral for use of hand splints, if necessary.
- F. Position hemiplegic patient in supine position.**
- (1) Place head of bed flat.
 - (2) Place folded towel or small pillow under shoulder or affected side.
 - (3) Keep affected arm away from body with elbow extended and palm up. (An alternative is to place arm out to side, with elbow bent and hand toward head of the bed.)
- Reduces extension of fingers and abduction of thumb. Maintains thumb slightly adducted and in opposition to fingers.
 - Necessary for positioning in supine position.
 - Decreases possibility of pain, joint contracture, and subluxation. Maintains mobility in muscles around shoulder to permit normal movement patterns.
 - Maintains mobility in arm, joints, and shoulder to permit normal movement patterns. (The alternative position counteracts limitation of ability of arm to rotate outward at shoulder [external rotation]. External rotation must be present to raise arm overhead without pain.)

Critical Decision Point: Position the affected hand in one of the recommended positions for flaccid or spastic hand.

- (4) Place a folded towel under the hip of patient's involved side.
 - (5) Flex affected knee 30 degrees by supporting it on a pillow or folded blanket.
 - (6) Support feet with soft pillows at a right angle to leg.
- G. Position patient in prone position:** This requires two staff members to safely position patient.
- (1) With drawsheet under patient, move patient toward one side of the bed. Ensure that side rail on opposite side is up for safety. With patient supine, roll patient over arm positioned close to body, with elbow straight and hand under hip. Position on abdomen in centre of the bed.
 - (2) Turn patient's head to one side and support head with a small pillow (see Step 12G[2] illustration).
- Diminishes effect of spasticity in entire leg by controlling hip position.
 - Slight flexion breaks up abnormal extension pattern of leg. Extensor spasticity is most severe when the patient is supine.
 - Maintains foot in dorsiflexion and prevents footdrop. Pillows prevent stimulation to ball of foot by hard surface, which has a tendency to increase muscle tone in a patient with extensor spasticity of lower extremity.
 - Positions patient correctly so that alignment can be maintained.
 - Diminishes effects of spasticity in entire leg by controlling hip position. Slight hip flexion breaks up abnormal extension pattern of leg; extensor spasticity is most severe when the patient is supine.
 - Reduces flexion or hyperextension of cervical vertebrae.

► SKILL 45-1 Moving and Positioning Patients in Bed—cont'd

[video](#)

- (3) Place small pillow under patient's abdomen below level of diaphragm (see Step 12G[3] illustration).

Step 12G(2) Prone position, head supported with pillow.

- (4) Support arms in flexed position, level at shoulders.
- (5) Support lower legs with pillows to elevate toes (see Step 12G[5] illustration).

Step 12G(5) Prone position with pillows supporting lower legs.

H. Position patient with hemiplegia in prone position.

- Reduces pressure on breasts of some female patients and decreases hyperextension of lumbar vertebrae and strain on lower back.

Step 12G(3) Prone position, pillow under patient's abdomen and feet.

- Maintains proper body alignment. Support reduces risk of joint dislocation.
- Prevents footdrop. Reduces external rotation of hips. Reduces mattress pressure on toes.

Critical Decision Point: Increase frequency of position changes if pressure areas begin to appear, joint mobility becomes impaired or worsened, or patient complains of discomfort. Consult with physiotherapist and occupational therapist as needed. Use 30-degree lateral position (see Chapter 46) to help prevent pressure ulcers.

- (1) Move patient toward unaffected side.
 - (2) Roll patient onto side.
 - (3) Place pillow on patient's abdomen.
 - (4) Roll patient onto abdomen by positioning involved arm close to patient's body, with elbow straight and hand under hip. Roll patient carefully over arm.
 - (5) Turn head toward involved side.
 - (6) Position involved arm out to side, with elbow bent, hand toward head of bed, and fingers extended (if possible).
 - (7) Flex knees slightly by placing pillow under legs from knees to ankles.
 - (8) Keep feet at right angle to legs by using a pillow high enough to keep toes off mattress.
- I. Position patient in lateral (side-lying) position.
- (1) Lower head of bed completely or as low as the patient can tolerate.
 - (2) Position patient to the side of the bed.
 - (3) Prepare to turn patient onto side. Flex patient's knee that will not be next to mattress. Place one hand on the patient's hip and one hand on the patient's shoulder.
 - (4) Roll patient onto side toward you.
- Creates room for proper patient alignment in centre of bed when patient is rolled onto abdomen.
 - Prevents sagging of abdomen when patient is rolled over; decreases hyperextension of lumbar vertebrae and strain on lower back.
 - Prevents injury to affected side.
 - Promotes development of neck and trunk extension, which is necessary for standing and walking.
 - Counteracts limitation of the arm's ability to rotate outward at the shoulder (external rotation). External rotation must be present to raise arm over head without pain.
 - Flexion prevents prolonged hyperextension, which could impair joint mobility.
 - Maintains feet in dorsiflexion.
 - Provides position of comfort for patient and removes pressure from bony prominences on back and buttocks.
 - Provides room for patient to turn to side.
 - Positioning will set up leverage for easy turning.
 - Rolling patient toward nurse decreases trauma to tissues. In addition, patient is positioned so that leverage on hip makes turning easy.

Continued

► SKILL 45-1 Moving and Positioning Patients in Bed—cont'd

video

- (5) Place pillow under patient's head and neck.
 - (6) Bring shoulder blade forward.
 - (7) Position both arms in a slightly flexed position. The upper arm is supported by a pillow level with the shoulder; the other arm, by the mattress.
 - (8) Place tuck-back pillow behind patient's back. (Make by folding pillow lengthwise. The smooth area is slightly tucked under the patient's back.)
 - (9) Place pillow under semiflexed upper leg level at hip from groin to foot (see Step 12I[9] illustrations).
- Maintains alignment. Reduces lateral neck flexion. Decreases strain on sternocleidomastoid muscle.
 - Prevents patient's weight from resting directly on shoulder joint.
 - Decreases internal rotation and adduction of the shoulder. Supports both arms in a slightly flexed position.
 - Provides support to maintain patient on side.
 - Maintains leg in correct alignment. Prevents pressure on bony prominence.

Step 12I(9) Side-lying position with pillows in place.

- (10) Place sandbag parallel to plantar surface of dependent foot.
- J. Position patient in Sims' (semiprone) position.**
- (1) Lower head of bed completely.
 - (2) Be sure patient is comfortable in supine position.
 - (3) Position patient in lateral position, with dependent arm straight along the patient's body and with patient lying partially on abdomen.
 - (4) Carefully lift patient's dependent shoulder and bring arm back behind the patient.
 - (5) Place a small pillow under patient's head.
 - (6) Place pillow under flexed upper arm, supporting arm level with shoulder.
 - (7) Place pillow under flexed upper leg, supporting leg level with hip.
 - (8) Place sandbags or pillows parallel to plantar surface of foot (see Step 12J[8] illustration).
- Maintains dorsiflexion of foot. Prevents footdrop.
 - Provides for proper body alignment while patient is lying down.
 - Prepares patient for position. Patient is rolled partially onto abdomen.
 - Maintains proper alignment and prevents lateral neck flexion. Prevents internal rotation of shoulder. Maintains alignment.
 - Prevents internal rotation of hip and adduction of leg. Flexion prevents hyperextension of leg. Reduces mattress pressure on knees and ankles.
 - Maintains foot in dorsiflexion. Prevents footdrop.

Step 12J(8) Sims' (semiprone) position with pillows in place.

K. Logroll the patient (this requires three nurses).

Critical Decision Point: Supervise and aid UCPs when a physician's order is to logroll a patient. Patients who have suffered from spinal cord injury or are recovering from neck, back, or spinal surgery often need to keep the spinal column in straight alignment to prevent further injury.

- (1) Place pillow between patient's knees.
 - (2) Cross patient's arms on chest.
- Prevents tension on the spinal column and adduction of the hip.
 - Prevents injury to arms.

► SKILL 45-1 Moving and Positioning Patients in Bed—cont'd

- (3) Position two nurses on side of bed to which the patient will be turned. Position third nurse on the other side of bed (see Step 12K[3] illustration).
- (4) Fanfold or roll the drawsheet or pull sheet.
- (5) Move the patient as one unit in a smooth, continuous motion on the count of 3 (see Step 12K[5] illustration).

Step 12K(3) Position nurses on each side of patient.

- (6) The nurse on the opposite side of the bed places pillows along the length of the patient (see Step 12K[6] illustration).
- (7) Gently lean the patient as a unit back toward the pillows for support (see Step 12K[7] illustration).

Step 12K(6) Place pillows along patient's back for support.

13. Perform hand hygiene.
14. Evaluate patient's level of comfort and ability to assist in position change.
15. After each position change, evaluate patient's body alignment and presence of any pressure areas. Observe for areas of erythema or breakdown involving skin.

Unexpected Outcomes

Joint contractures

Skin erythema and breakdown

Patient avoids moving

Recording and Reporting

- Record procedure and observations (e.g., condition of skin, joint movement, patient's ability to assist with positioning).
- Report observations at change of shift and document in nurses' notes.

Home Care Considerations

- Teach the family about the importance of body mechanics for themselves and the patient.
- Teach the patient and family about the signs of skin breakdown and the importance of safety during positioning patients with decreased sensation or mobility.

- Distributes weight equally among nurses.
- Provides strong handles to grip the drawsheet or pull sheet without slipping.
- Maintains proper alignment by moving all body parts at the same time, preventing tension or twisting of the spinal column.

Step 12K(5) Move patient as a unit, maintaining proper alignment.

- Pillows keep the patient aligned.
- Ensures continued straight alignment of spinal column, preventing injury.

Step 12K(7) Gently lean patient as a unit against pillows.

- Reduces transmission of microorganisms.
- Patients with reduced activity tolerance and increased levels of pain may find position changes very tiring and will need post-position change interventions to restore their level of comfort.
- Prompt identification of poor alignment reduces risks to the patient's skin and musculoskeletal systems.

Related Interventions

- Improper positioning results in shortening of muscles.
- Frequency of repositioning is inadequate.
- Place turning schedule above patient's bed.
- Frequency of repositioning is inadequate.
- Place turning schedule above patient's bed.

benefits for patients with acute respiratory distress syndrome and acute lung injury (Marklew, 2006).

Assess for and correct any of the following potential trouble points for patients in the prone position (see Skill 45-1 for preventive measures):

- Neck hyperextension
- Hyperextension of the lumbar spine
- Plantar flexion of the ankles
- Unprotected pressure points at the chin, elbows, hips, knees, and toes

Side-Lying Position. In the side-lying (or lateral) position, the patient is resting on the side with the major portion of body weight on the dependent hip and shoulder. A 30-degree lateral position is recommended for patients at risk for pressure ulcers (see Chapter 46). Trunk alignment should be the same as in standing. For example, the structural curves of the spine should be maintained, the head should be supported in line with the midline of the trunk, and rotation of the spine should be avoided. The following trouble points are common in the side-lying position (see Skill 45-1 for preventive measures):

- Lateral flexion of the neck
- Spinal curves out of normal alignment
- Shoulder and hip joints internally rotated, adducted, or unsupported
- Lack of support for the feet
- Lack of protection for pressure points at the ear, shoulder, anterior iliac spine, trochanter, and ankles
- Excessive lateral flexion of the spine if the patient has large hips and a pillow is not placed superior to the hips at the waist

Sims' Position. Sims' position differs from the lateral position in the distribution of the patient's weight. In Sims' position, the weight is placed on the anterior ilium, humerus, and clavicle. Trouble points common in Sims' position include the following (see Skill 45-1 for preventive measures):

- Lateral flexion of the neck
- Internal rotation, adduction, or lack of support to the shoulders and hips
- Lack of support for the feet
- Lack of protection for pressure points at the ilium, humerus, clavicle, knees, and ankles

Transfer Techniques. Nurses often provide care for patients who must be assisted to change positions, who must be moved up in bed, or who must be transferred from a bed to a chair or from a bed to a stretcher. Use of proper body mechanics will enable you to position, move, or transfer patients safely and also protect you from injury to the musculoskeletal system (see Chapter 35). Although many transfer techniques are used, the following general guidelines should be followed in any transfer procedure:

- Raise the side rail on the side of the bed opposite you to prevent the patient from falling out of bed.
- Elevate the level of the bed to a comfortable working height.
- Assess the patient's mobility and strength to determine what assistance the patient can offer during transfer.
- Determine the need for assistance from other care providers or mechanical lifts.
- Explain the procedure to the patient and describe what is expected of the patient.
- Assess for correct body alignment and pressure areas after each transfer.

safety alert Recognition of your own personal strengths and limits is crucial. Moving a patient who is completely immobilized alone is dangerous and not allowed in many agencies. If you are attempting transfer or moving techniques for the first time, you should request help to reduce the risk of injury to yourself and to the patient.

Moving Patients. Patients require various levels of assistance to move up in bed, move to the side-lying position, or sit up at the side of the bed. For example, a young, healthy woman may need only a little support as she sits at the side of the bed for the first time after childbirth, whereas an older person may need help from one or more nurses to do the same task one day after abdominal surgery.

Always enlist the patient's help to the fullest extent possible. To determine what the patient is able to do alone and how many people are needed to help move the patient in bed, you need to assess the patient to determine whether the illness contradicts exertion (e.g., cardiovascular disease).

Next, determine whether the patient comprehends what is expected. For example, a patient recently medicated for post-operative pain may be too lethargic to understand instruction. To ensure safety, two nurses would be needed to move the patient in bed. You must then determine the comfort level of the patient and evaluate personal strength and knowledge of the procedure.

Finally, determine whether the patient is too heavy or immobile for you to complete the procedure alone (see Skill 45-1). If in doubt, always request assistance from another person. Collaborate with the physiotherapist, occupational therapist, and physician to plan for mobilizing the **bariatric** patient (Box 45-9). Use of mechanical transfer devices may be warranted (Figure 45-18), and agency lifting and transferring policies must be followed (Worksafe BC, 2006).

Assessment criteria and tools have been developed to help you gather data and to assess and plan for the safe transfer of patients. An example of a patient mobility assessment form is shown in Table 45-4.

Transferring a Patient from a Bed to a Chair. Transfer of a patient from a bed to a chair by one nurse requires assistance from the patient and should not be attempted with a patient who cannot help (Skill 45-2). Explain the procedure to the patient before the transfer. Moving obstacles out of the way also prepares the environment. The chair is placed next to the bed with the chair back in the same plane as the head of the bed. Placement of the chair allows you to pivot with the patient and to transfer the patient's weight in a controlled manner.

A safe transfer is the first priority. If you are doubtful about personal strength or the patient's ability to help, you should request assistance. A **transfer belt** should be used with all patients being transferred for the first time and thereafter as deemed necessary. Use of a transfer belt (called a **gait belt** when used for walking with a patient) helps prevent caregiver back injuries and aids in the safe transfer of the patient. The belt encircles the patient's waist and has handles attached for the nurse to hold. It is applied over the patient's clothing, never over bare skin. The belt is tightened so that it is snug but does not cause discomfort or impair breathing, and the buckle is placed off-centre in the front or in the back. The buckle should not be over the spine.

The patient should sit and dangle the feet at the side of the bed for a minute before standing. The patient should then stand at the side of the bed for another minute so that he or

► BOX 45-9 Mobilizing Bariatric Patients

Several measures are used to evaluate a patient's weight status. One such measure, the body mass index (BMI), expresses the relative percentages of fat and muscle mass; weight in kilograms is divided by height in metres. The result is used as an index of obesity.

The World Health Organization uses the BMI to categorize weight status:

- BMI 25 to 29.9: grade I, moderately overweight
- BMI 30 to 39.9: grade II, severely obese
- BMI >40: grade III, massively or morbidly obese

The Canadian Medical Association has declared obesity an "epidemic" (Lau et al., 2007). A survey conducted in 2004 reported that 59% of the adult population is overweight (BMI 25 to 29.9) and 23% is obese (BMI 30 to 39.9) (Starky, 2005).

Mobilizing bariatric patients requires special considerations beyond that outlined for mobilizing most patients. Facilities need policies and procedures that describe the safe handling practices and available equipment to mobilize bariatric patients. Staff need training in the techniques and use of equipment specifically for the care of this patient population (Muir & Archer-Heese, 2008). Nurses should consult their policy manual, contact their occupational health department, or consult with their administrator for organization-specific guidelines.

One of the major considerations in mobilizing bariatric patients is to ensure that the environment is safe. Environments need to be larger than usual to accommodate the patient and the necessary equipment. Unfortunately, few care facilities are specially designed to accommodate such patients (Muir & Archer-Heese, 2009). Sometimes a bed must be blocked, allowing a two-bed space in which to care for the bariatric patient (Muir & Archer-Heese, 2008).

Another consideration is how much the bariatric patient is able to assist in the move. Specific assessment forms for the safe mobilization of the bariatric patient have been developed (Muir & Archer-Heese, 2008; Muir & Archer-Heese, 2009; Muir & Gerlach, 2003).

You will need to collaborate with team members such as the physiotherapist and occupational therapist to plan for mobilizing. You may need to use a mechanical transfer device, preferably a ceiling lift. Specially designed equipment needed for moving a bariatric patient includes a hospital gown, blood pressure cuff, wheelchair, walker, commode, bed, chair, transfer device and lift, and overbed trapeze and grab bar. An overbed trapeze and grab bars enable the patient to be more independent and to participate in mobilizing (Muir & Archer-Heese, 2009).

she can quickly sit down on it in case of dizziness or fainting (Dingle, 2003). When moving a patient from a bed to a wheelchair, both nurses must use proper body mechanics. If a patient has an immobile lower extremity from a cast or paralysis, the transfer should be toward the unaffected leg.

Transferring a Patient from a Bed to a Stretcher. To transfer a patient who is immobile from a bed to a stretcher or from a bed to another bed, use a friction-reducing device under the patient. In this technique, nurses need to be on opposite sides of the bed and holding on to the friction-reducing device. The stretcher and the bed are placed side by side so that the patient can be transferred quickly and easily using the device. As with all procedures, safety is the priority. To increase safety, the three team members need to work together, with one person assuming the leadership role.

Exercise caution when transferring a patient who has or is suspected of having spinal cord trauma. If the patient must be

moved, a transfer board should be placed under the patient to maintain spinal alignment before transferring the patient to a stretcher. The patient should be prepared for the transfer and asked to help when possible (e.g., by folding the arms over the chest). The environment should be free from obstacles, and unnecessary equipment should be removed from the bed.

Restorative Care. The goal of restorative care for the patient who is immobile is to maximize functional mobility and independence and reduce residual functional deficits such as impaired gait and decreased endurance. The focus in restorative care is on not only ADLs that relate to physical self-care but also **instrumental activities of daily living (IADLs)**. IADLs are activities that are necessary to be independent in society beyond eating, grooming, transferring, and toileting. They include such skills as shopping, preparing meals, banking, and taking medications.

Although you will use many of the interventions described in the "Health Promotion" and "Acute Care" sections, the emphasis here is on working collaboratively with patients and their significant others and with other health care providers. The goal is to enhance the patient's quality of life by helping the patient return to maximal functional ability in both ADLs and IADLs.

Intensive specialized rehabilitation such as occupational or physiotherapy is common. If the patient is in an institution, he or she will likely go to the therapy department two to three times a day. Your role is to work collaboratively with these professionals and reinforce exercises and teaching. For example, after a stroke, a patient will likely receive gait training from a physiotherapist, speech rehabilitation from a speech therapist, and training from an occupational therapist on getting dressed and preparing food. Working with allied health providers on an interdisciplinary plan of care, you can reinforce and further enhance the patient's mobilization. The therapy may not be able to restore total functional health, but it may help the patient adapt to limited mobility and related complications.

Restorative interventions are focused on the regaining of mobility. According to evidenced-informed protocols, common restorative interventions used by nurses include promotion of exercises for maintaining or regaining joint mobility and teaching of the use of assistive devices for walking (Box 45-10). Items frequently used to help a patient adapt to mobility limitations include walkers, canes, wheelchairs, and assistive devices such as raised toilet seats, reaching sticks, special silverware, and adaptive clothing with Velcro closures.

Joint Mobility. To ensure adequate joint mobility, teach the patient about ROM exercises. When the patient does not have voluntary motor control, start the patient on passive ROM exercises. Walking also increases joint mobility. Occasionally, patients need to use assistive devices such as crutches or walkers to help them walk.

Range-of-Motion Exercises. Patients with restricted mobility are unable to perform some or all ROM exercises independently. Such patients include those with limited movement in one extremity and those who are completely immobilized. Provide ROM exercises to maintain maximum joint mobility.

To ensure that patients routinely receive ROM exercises, schedule them at specific times, perhaps with another nursing activity, such as during the patient's bath. Doing so will enable you to systematically reassess mobility while improving the

Figure 45-18 A1, Ensure that safety straps are secured appropriately when using a motorized lift to help a patient move to standing position. A2, Patient grasps handles as the nurse enables motorized lift. A3, Patient is in standing position with feet on the floor and is ready to ambulate to a chair with nurses' help. B1, When the patient is unable to walk, secure safety straps, and use platform of the motorized lift. B2, Patient in upright position. B3, Position patient in front of chair. B4, Explain to patient the need to hold on to the handles as motorized lift begins to lower patient into chair. B5, Guide patient into chair.

TABLE 45-4 Patient Mobility Assessment Summary Form

This assessment form helps caregivers to determine if it is appropriate to assist the patient using a physical transfer or a mechanical lift. If the answer to any of the questions on the assessment form is “no,” then a mechanical lift should be used for the safety of the patient and caregivers. After determining whether the type of assistance is a physical transfer or mechanical lift, you must decide which type of transfer is most appropriate (see Skill 45-2).

Question	If All Are “Yes”	Then Transfer (Identify Type of Transfer)	If Any Are “No”	Then Lift (Identify Type of Lift)
Can the patient bear weight through one leg or both arms, to be moved from one surface to another?				
Is the patient consistent and reliable in bearing weight?				
Can the patient communicate with you?				
Can the patient follow commands?				
Is the patient free from pain or medical devices that may interfere with carrying out the procedure?				
Is the patient cooperative?				
Is the patient’s behaviour nonaggressive?				
Is the patient’s range of motion suitable for performing transfer?				
Is the patient’s strength suitable for performing a transfer?				
Are the patient’s mobility and balance suitable for performing a transfer?				
Are all environmental factors suitable?				
Are all equipment factors suitable?				
Are all caregivers able to perform the task?

SKILL 45-2 Using Safe and Effective Transfer Techniques**video****Delegation Considerations**

The skills of effective transfer techniques can be delegated to unregulated care providers (UCPs). Patients who are transferred for the first time after prolonged bed rest, extensive surgery, critical illness, or spinal cord trauma usually require supervision by professional nurses. When delegating this skill, it is important to instruct the UCP about the following:

- The need to seek assistance before moving or lifting a heavy patient.
- Any patient limitations that may affect safe transfer techniques.

Procedure**STEPS**

1. Assess the patient for the following:

- A. Muscle strength (legs and upper arms)
- B. Joint mobility and contracture formation

Equipment

- Transfer belt, sling, or lapboard (as needed), nonskid shoes, bath blankets, pillows
- Wheelchair: Position chair at 45-degree angle to bed, lock brakes, remove footrests, lock bed brakes.
- Stretcher: Position at right angle (90 degrees) to bed, lock brakes on stretcher, lock brakes on bed.
- Mechanical or hydraulic lift: Use ceiling track or mechanical portable lift, and sling.

RATIONALE

- Provides information relative to the patient’s abilities, physical status, and ability to comprehend. The number of individuals needed to provide a safe transfer can then be determined.
- Patients who are immobile have decreased muscle strength, tone, and mass. Affects ability to bear weight or raise body.
- Immobility or inflammatory processes (e.g., arthritis) may lead to contracture formation and impaired joint mobility.

Continued

► SKILL 45-2 Using Safe and Effective Transfer Techniques—cont'd

C. Paralysis or paresis (spastic or flaccid)

D. Orthostatic hypotension

E. Activity tolerance

F. Presence of pain

G. Vital signs

2. Assess patient's sensory status:

A. Adequacy of central and peripheral vision

B. Adequacy of hearing

C. Loss of sensation

- Patient with central nervous system damage may have bilateral paralysis (requiring transfer by swivel bar, sliding bar, or mechanical lift) or unilateral paralysis, which requires belt transfer to "best" (unaffected) side. Weakness (paresis) requires stabilization of knee during transfer. Flaccid arm must be supported with sling during transfer.
- Determines risk of fainting or falling during transfer. Patients who are immobile may have decreased ability for autonomic nervous system to equalize blood supply, resulting in drop of 20 mm Hg or more in systolic blood pressure or 10 mm Hg in diastolic blood pressure when rising from sitting position.
- Determines ability of patient to assist with transfer.
- Pain may reduce patient's motivation and ability to be mobile. Pain relief before transfer enhances patient participation.
- Vital sign changes such as increased pulse and respiration may indicate activity intolerance (see Chapter 30).

- Determines influence of sensory loss on ability to make transfer. Visual-field loss may decrease patient's ability to transfer safely. Patients with visual and hearing losses need transfer techniques adapted to deficits. Patients with cerebrovascular accident (CVA) may lose area of visual field, which profoundly affects vision and perception.

Critical Decision Point: Patients with hemiplegia also may "neglect" one side of the body (inattention to or unawareness of one side of body or environment), which distorts perception of the visual field.

3. Assess patient's cognitive status.

- Determines patient's ability to follow directions and learn transfer techniques.

Critical Decision Point: Patients with head trauma or CVA may have perceptual cognitive deficits that create safety risks. If patient has difficulty in comprehension, simplify instructions and maintain consistency.

4. Assess patient's level of motivation:

A. Patient's eagerness or unwillingness to be mobile

B. Whether patient avoids activity and offers excuses

5. Assess previous mode of transfer (if applicable).

6. Assess patient's specific risk of falling when transferred.

7. Assess special transfer equipment needed for home setting.
Assess home environment for hazards.

8. Perform hand hygiene.

9. Explain procedure to patient.

10. Transfer patient:

A. Assist patient to sitting position.

(1) Place patient in supine position.

(2) Face head of bed at a 45-degree angle and remove pillows.

(3) Place feet apart with foot nearer bed behind other foot, continuing at a 45-degree angle to the head of the bed.

- Altered psychological states reduce the patient's desire to engage in activity.
- Determines mode of transfer and assistance required to provide continuity. Transfer belts should be used with all patients being transferred for the first time and thereafter as deemed necessary.
- Certain conditions increase the patient's risk of falling or potential for injury. Neuromuscular deficits, motor weakness, calcium loss from long bones, cognitive and visual dysfunction, and altered balance increase the risk of falls.
- Transfer ability at home is greatly enhanced by prior teaching of family and support people, and assessment of home for safety risks and functionality.
- Reduces transmission of microorganisms.
- Increases patient participation.
- Enables nurse to assess patient's body alignment continually and to administer additional care, such as suctioning or hygiene needs.
- Proper positioning reduces twisting of nurse's body when moving the patient. Pillows may cause interference when the patient is sitting up in bed.
- Improves balance and allows transfer of body weight as patient is sitting up in bed.

► SKILL 45-2 Using Safe and Effective Transfer Techniques—cont'd

video

- (4) Place hand farther from patient under shoulders, supporting patient's head and cervical vertebrae.
- (5) Place other hand on bed surface.
- (6) Raise patient to sitting position by shifting weight from front to back leg. Pivot feet as weight is shifted from front to back leg so that the upper body does not twist.
- (7) Push against bed with arm that is placed on bed surface.

- Maintains alignment of head and cervical vertebrae and allows for even lifting of patient's upper trunk.
- Provides support and balance.
- Improves balance, overcomes inertia, and transfers weight in direction in which patient is being moved.

B. Assist patient to sitting position on side of bed with bed in low position.

- (1) Turn patient to side facing you on side of bed on which patient will be sitting (see Step 10B[1] illustration).

Step 10B(1) Side-lying position.

- (2) Raise head of bed 30 degrees.
- (3) Stand opposite patient's hips. Turn diagonally so that you face patient and far corner of foot of bed.
- (4) Place feet apart with foot closer to head of bed in front of other foot.
- (5) Place arm nearer head of bed under patient's shoulders, supporting head and neck.
- (6) Place other arm over patient's thighs (see Step 10B[6] illustration).
- (7) Move patient's lower legs and feet over side of bed. Pivot toward rear leg, allowing patient's upper legs to swing downward.
- (8) At the same time, shift weight to rear leg and elevate patient (see Step 10B[8] illustration). Pivot feet in the direction of movement to avoid twisting of upper body.

- Divides activity between arms and legs and protects back from strain. By bracing one hand against the mattress and pushing against it as patient is lifted, part of the weight that would be lifted by the back muscles is transferred through the arm onto the mattress.
- Decreases amount of work needed by patient and nurse to raise patient to sitting position.

Step 10B(6) Nurse places arm over patient's thighs.

C. Transfer patient from bed to chair with bed in low position.

- (1) Assist patient to sitting position on side of bed. Have chair in position at 45-degree angle to bed. If the patient has hemiparesis or hemiplegia, place the chair on the patient's unaffected side.

- Prepares patient to move to side of bed and protects patient from falling.
- Places nurse's centre of gravity nearer patient. Reduces twisting of nurse's body by facing the direction of movement.
- Increases balance and allows nurse to transfer weight as patient is brought to sitting position on side of bed.
- Maintains alignment of head and neck as nurse brings patient to sitting position.
- Supports hip and prevents patient from falling backward during procedure.
- Decreases friction and resistance. Weight of patient's legs when off the bed allows gravity to pull down lower legs, and weight of legs assists in pulling upper body into sitting position.
- Reduces patient risk for falling. Patients who have been immobilized may experience lightheadedness or dizziness when assuming a sitting position.

Step 10B(8) Nurse shifts weight to rear leg and elevates patient.

- Positions chair within easy access for transfer. Enables the patient to transfer more safely by pivoting on the unaffected leg and reaching for the arm of the chair with the unaffected arm.

Continued

► SKILL 45-2 Using Safe and Effective Transfer Techniques—cont'd

- (2) Apply transfer belt or other transfer aids.
 - (3) Ensure that patient has stable nonskid shoes. Weight-bearing or unaffected (strong) leg is placed back with the affected (weak) knee slightly forward or parallel.
 - (4) Place feet shoulder-width apart.
 - (5) Flex hips and knees, supporting patient's weaker knee or leg with your knees (see Step 10C[5] illustration).
 - (6) Grasp transfer belt from underneath.
- Transfer belt maintains stability of patient during transfer and reduces risk of falling (Owen et al., 1999). Patient's arm should be in a sling if flaccid paralysis is present.
 - Nonskid soles decrease risk of slipping during transfer. Always have patient wear shoes during transfer; bare feet increase risk of falls. Patient will stand on unaffected (stronger, or weight-bearing) leg.
 - Ensures balance with wide base of support.
 - Flexion of knees and hips lowers the centre of gravity to object to be raised; supporting knees with nurse's knees allows for stabilization of patient's knee when the patient stands.
 - Transfer belt is grasped at patient's side to provide movement of patient at centre of gravity. Patients with upper extremity paralysis or paresis should never be lifted by or under the arms.

Critical Decision Point: A transfer belt or gait belt with handles should be used in place of the under-axilla technique. The under-axilla technique has been found to be physically stressful for nurses and uncomfortable for patients.

- (7) Rock patient up to standing position on count of 3 while straightening hips and legs and keeping knees slightly flexed (see Step 10C[7] illustration). Unless contraindicated, patient may be instructed to use hands to push up if applicable.
- Rocking motion gives patient's body momentum and requires less muscular effort for the nurse to lift patient.

Step 10C(5) Nurse flexes hips and knees, supporting patient's knee between nurse's knees.

- (8) Maintain stability of patient's weak or paralyzed leg between your knees.
- (9) Pivot on foot farther from chair. Instruct patient to stand straight. Pivot body in direction of chair, instructing patient to take small steps toward chair. Ask patient to tell you when the chair touches the back of his or her knees.

Step 10C(7) Nurse rocks patient to standing position.

- Ability to stand can often be maintained in a paralyzed or weak limb with support of nurse's knees to stabilize it.
- Maintains support of patient while allowing adequate space for patient to move.

► **SKILL 45-2 Using Safe and Effective Transfer Techniques—cont'd**

video

- (10) Instruct patient to use armrests on chair for support and ease patient into chair (see Step 10C[10] illustration).
- (11) Flex hips and knees while lowering patient into chair (see Step 10C[11] illustration).

- Increases patient stability.
- Prevents injury to nurse from poor body mechanics.

Step 10C(10) Patient uses armrests for support.

Step 10C(11) Nurse flexes hips and knees while easing patient into chair.

- (12) Assess patient for proper alignment for sitting position. Provide support for paralyzed extremities. Lapboard or sling will support flaccid arm. Stabilize leg with bath blanket or pillow.
- (13) Praise patient's progress, effort, or performance.

- Prevents injury to patient from poor body alignment.
- Continued support and encouragement provide incentive for the patient to persevere with these efforts.

D. Transfer patient from bed to stretcher or other bed, using drawsheet or friction-reducing device.

- (1) Place bed flat, and position at same level as stretcher. Ensure that bed brakes are locked.
- (2) Lower side rails. Have two caregivers stand on the side where the stretcher will be, while the third caregiver stands on the other side.
- (3) Two caregivers help patient roll onto side toward one caregiver.
- (4) Work together to position friction-reducing device properly under patient's back (see Step 10D[4] illustration).
- (5) Roll stretcher along side of bed. Lock wheels of stretcher once it is in place. Instruct patient to place arms across chest and not to move.
- (6) All three caregivers place feet widely apart with one foot slightly in front of the other, and grasp the friction-reducing device.

- Bed and stretcher need to be at the same level to allow patient to slide from bed to stretcher.
- Minimizes caregiver's stretching. Prevents patient from falling out of bed and promotes safety.
- Positions patient for friction-reducing lateral transfer device.
- Patient needs to be placed on transfer device properly to enable safe transfer.
- Positions stretcher correctly for transfer and prevents patient from falling out of bed.
- Prepares for transfer. Wide base of support allows nurse to shift weight and minimizes back strain.

Continued

► SKILL 45-2 Using Safe and Effective Transfer Techniques—cont'd

video

- (7) On the count of 3, caregivers pull the patient from the bed onto the stretcher, using the friction-reducing device and shifting weight appropriately (see Step 10D[7] illustration).

Step 10D(4) Two caregivers position sliding board under patient.

- (8) Put up side rail of stretcher on side where caregivers are, then roll stretcher away from side of bed and put side rails up on that side.
- E.** Use mechanical or hydraulic lift to transfer patient from bed to chair. Before using lift, be thoroughly familiar with its operation. Gather all necessary equipment and caregivers.
- (1) Choose the appropriate-size sling for patient's weight and height. Position lift properly at bedside.
 - (2) Position chair near bed, and allow adequate space to manoeuvre lift.
 - (3) Raise bed to a high position with mattress flat. Lower side rail.
 - (4) Keep bed side rail up on the side opposite you.
 - (5) Roll patient on side away from you.
 - (6) Place sling under patient. Place lower edge under patient's knees (wide piece); upper edge fits under patient's shoulders (narrow piece).
 - (7) Roll patient to opposite side and pull sling through.
 - (8) Roll patient supine onto sling.
 - (9) Remove patient's glasses, if present.
 - (10) If using transportable Hoyer lift, place lift's horseshoe bar under side of bed (on side with the chair).
 - (11) Lower horizontal bar to sling level by releasing hydraulic valve. Lock valve.
 - (12) Attach hooks on strap to holes in sling. Short straps hook to top holes of sling; longer straps hook to bottom of sling.
 - (13) Elevate head of bed.
 - (14) Fold patient's arms over chest.
 - (15) Use lift to raise patient off the bed and manoeuvre to chair (see Step 10E[15] illustration).

- Transfers patient smoothly and efficiently to the stretcher.

Step 10D(7) Transfer of patient from bed to stretcher, using friction-reducing device.

- Side rails prevent patient from falling off stretcher.
- Ensures safe elevation of patient off bed.
- Prepares environment for safe use of lift and subsequent transfer.
- Maintains nurses' alignment during transfer.
- Maintains patient safety.
- Allows positioning of patient on mechanical or hydraulic sling.
- Places sling under patient's centre of gravity and greatest portion of body weight.
- Completes positioning of patient on mechanical or hydraulic sling.
- Sling should extend from shoulders to knees (hammock) to support patient's body weight equally.
- Swivel bar is close to patient's head and could break eyeglasses.
- Positions lift efficiently and promotes smooth transfer.
- Positions hydraulic lift close to patient. Locking valve prevents injury to patient.
- Secures hydraulic lift to sling.
- Positions patient in sitting position.
- Prevents injury to paralyzed arms.

SKILL 45-2 Using Safe and Effective Transfer Techniques—cont'd

(16) Position patient and lower slowly into chair (see Step 10E[16] illustration).

Step 10E(15) Use mechanical lift to raise patient off the bed.

(17) Close check valve as soon as patient is down, and release straps.

(18) Remove straps and mechanical or hydraulic lift.

(19) Check patient's sitting alignment and correct it if necessary.

11. Perform hand hygiene.

12. With each transfer, evaluate patient's tolerance and level of fatigue and comfort.

13. After each transfer, evaluate patient's body alignment.

Not all patients require a fully mechanically assisted lift. Many types of lifts allow patients to partially weight bear. Benefits of these types of lifts include practice at standing, promotion of independence and control, and fostering of a sense of safety and confidence for patients who may have been immobile for a long period of time. An example of a lift that allows for partial weight bearing is the SERA Lift. Before using any lift, you should receive instruction and practise this skill (see Figure 45-19).

Unexpected Outcomes

Patient inability to comprehend and follow directions

Patient injury on transfer

Patient too weak for active transfer

Weight on non-weight-bearing limb

Uneven patient ability for transfer

Inability to stand during transfer

Localized areas of persistent erythema

• Moves patient from bed to chair.

Step 10E(16) Use mechanical lift to lower patient into the chair.

- If valve is left open, boom may continue to lower and injure patient.
- Prevents damage to skin and underlying tissues from canvas or hooks.
- Prevents injury from poor posture.
- Reduces transmission of microorganisms.
- Increased activity may result in symptoms associated with activity intolerance (e.g., increased pulse, changes in blood pressure, increased respirations, and decreased level of comfort). These patients may find transfer very tiring and will need post-transfer interventions to restore their level of comfort.
- Prompt identification of poor alignment reduces risks to the patient's skin and musculoskeletal systems.

Related Interventions

- Cognitive impairment affects learning and retention.
- Reassess continuity and simplicity.
- Cognitive impairment affects learning and retention.
- Reassess continuity and simplicity.
- Physical impairments require increased assistance from nursing personnel.
- Increase patient's bed activity and exercise to heighten tolerance.
- Certain conditions (e.g., hip fractures that have not been surgically stabilized) need to be non-weight bearing through the healing process.
- Reassess patient's understanding of weight-bearing status.
- Transfers may be difficult when the patient is fatigued or in pain. Assess the patient's ability before transfer (allow for a rest period before transferring, or medicate for pain if indicated).
- Periodic confusion may also alter performance.
- This results from increased fatigue, orthostatic hypotension, or pain.
- Provide for adequate assistance during transfer.
- Perform complete assessment of pressure ulcers and carry out appropriate interventions (see Chapter 46).

Continued

► SKILL 45-2 Using Safe and Effective Transfer Techniques—cont'd

video

Recording and Reporting

- Record procedure, including the following pertinent observations: patient's weakness, ability to follow directions, weight-bearing ability, balance, and ability to pivot; number of personnel needed to assist; and amount of assistance (muscle strength) required.
- Report any unusual occurrence to the nurse in charge. Report transfer ability and assistance needed to next shift or other caregivers. Report progress or remission to rehabilitation staff (physiotherapist or occupational therapist).

Home Care Considerations

- Teach family members about proper body mechanics for themselves and the patient.
- Provide community resources for hospital equipment that can be used in the home setting (e.g., transfer belts, mechanical lifts) to assist in safe transfer techniques.

* BOX 45-10

EVIDENCE-INFORMED PRACTICE GUIDELINE

Exercise Promotion: Reinitiating Exercise in the Patient Who Was Previously Immobile

- Encourage patient to contemplate change in activity level.
- Increase patient's awareness of current activity levels.
- Provide information about the benefits of exercise.
- Determine any impediments to exercise.
- Provide choices of physical activities.
- Assist patient in preparing for an activity program.
- Provide information about how to safely carry out the exercise (e.g., proper walking, safety considerations).
- Assist patient in strengthening exercise tolerance and activity levels.
- Emphasize patient's ability to become more active.
- Provide resources for social exercise groups (e.g., fitness groups, community walking programs, walking in local shopping malls).
- Assist patient in establishing an activity program.
- Provide positive, constructive feedback.
- Increase physical activity as appropriate for patient's mobility status.
- Assist patient in developing a long-term exercise plan.
- Visit the patient while he or she is participating in an exercise program.
- Assist patient in maintaining an activity program.
- Recognize each success.
- If relapse occurs, remind patient that it is okay and to continue with the exercise program.
- Maintain a supportive environment.
- Encourage family and friends to participate in the exercise program.

Figure 45-19 Using a cupped hand to support a joint.

you may support an extremity while the patient performs the movement, or the patient may be able to move some joints actively while you passively move others. In general, exercises should be as active as health and mobility allow. Passive ROM exercises should begin as soon as the patient's ability to move the extremity or joint is lost. Movements are carried out slowly and smoothly, just to the point of resistance, and should not cause pain. Never force a joint beyond its capacity. Each movement should be repeated five times during the session.

When performing passive ROM exercises, stand at the side of the bed closest to the joint being exercised. Passive ROM exercises are performed using a head-to-toe sequence and moving from larger to smaller joints. If an extremity is to be moved or lifted, place a cupped hand under the joint to support it (Figure 45-19), support the joint by holding the adjacent distal and proximal areas (Figure 45-20), or support the joint with one hand and cradle the distal portion of the extremity with the remaining arm (Figure 45-21). The following sections provide an overview of nursing considerations for ways to support major joints in the body. See Table 45-2 for detailed ROM exercises and illustrated motion for each joint.

Neck. A flexion contracture of the neck is a serious disability because the patient's neck is permanently flexed with the chin close to or actually touching the chest. Ultimately, the patient's body alignment is altered, the visual field is changed, and the level of independent functioning is decreased.

Shoulder. The shoulder is controlled by the deltoid muscle and rotator cuff muscles. When caring for a patient with limited shoulder mobility, you may need to provide support devices for the shoulder, such as slings when the patient is standing or sitting, or pillows when the patient is in bed. Correctly positioning the shoulder prevents pain, joint subluxation, and further changes in body alignment.

patient's ROM. In addition, during bathing, the extremities and joints are usually put through complete ROM.

Unless contraindicated, the care plan should include movement of the patient's extremities through the fullest ROM possible. ROM exercises may be active, passive, or somewhere in between (active assisted). With a weak patient, for example,

Figure 45-20 Supporting the joint by holding the distal and proximal areas adjacent to the joint.

Figure 45-21 Cradling the distal portion of an extremity.

Elbow. The elbow functions optimally at an angle of about 90 degrees. An elbow fixed in full extension is disabling and limits the patient's independence.

Forearm. Most functions of the hand are best carried out with the forearm in moderate pronation. When the forearm is fixed in a position of full supination, the patient's use of the hand is limited.

Wrist. The primary function of the wrist is to place the hand in slight extension, the position of functioning. Therefore, full ROM is not as great a priority as maintaining the wrist in a functional position. When the wrist is fixed in even a slightly flexed position, the grasp is weakened. In the patient who is immobilized, the functional position of the wrist can be achieved by using splints.

Fingers and Thumb. The ROM in the fingers and thumb enables the patient to perform ADLs and activities requiring fine motor skills, such as writing, carpentry, needlework,

drawing, and painting. The functional position of the fingers and thumb is slight flexion of the thumb in opposition to the fingers.

Hip. Because the lower extremities are involved chiefly with locomotion and weight bearing, stability of the hip joint may be more important than its mobility. For example, if the hip has no mobility but is fixed in a neutral position and fully extended, it is possible to walk without a significant limp.

Contractures often fix the hip in positions of deformity. Excessive abduction makes the affected leg appear too short, whereas excessive adduction makes the affected leg appear too long. In either case, the patient has limited mobility and walks with an obvious limp. Internal and external rotation contractures cause an abnormal and unbalanced gait.

Knee. A primary function of the knee is stability, which is achieved by ROM, ligaments, and muscles. However, the knees cannot remain stable under weight-bearing conditions unless quadriceps power is adequate for maintaining the knee in full extension. ROM exercises should include pulling the knee into full extension.

An immobile knee joint can result in serious disability. The degree of disability depends on the position in which the knee is stiffened. If the knee is fixed in full extension, the person must sit with the leg thrust out in front. When the knee is flexed, the person limps while walking. The greater the flexion, the greater is the limp.

Ankle and Foot. Without full ROM of the ankle, gait deviations will occur. If the joint is not stable, the person will fall. If joint mobility is diminished, you should maintain the joint in a position in which walking can be carried out with a forward rolling motion from the heel onto the forefoot.

When the person relaxes as in sleep or coma, the foot relaxes and assumes a position of plantar flexion. As a result, the foot may become fixed in plantar flexion (footdrop), which impairs the ability to walk. Inversion and eversion must also be avoided to allow the foot to rest flat on the floor.

Toes. Excessive flexion of the toes results in clawing. When this is a permanent deformity, the foot is unable to rest flat on the floor and the patient is unable to walk properly. Flexion contractures are the most common foot deformity associated with reduced joint mobility.

Adequate ROM provides the necessary mobility to carry out ADLs and exercise. In addition, adequate ROM in the lower extremities allows walking.

Walking. In the normal walking posture, the head is erect; the cervical, thoracic, and lumbar vertebrae are aligned; the hips and knees have appropriate flexion; and the arms swing freely with the legs. Illness or trauma can reduce activity tolerance, so that assistance in walking is required. In addition, temporary or permanent damage to the musculoskeletal and nervous systems may necessitate use of an assistive device for walking.

Helping a Patient Walk. When a patient's mobility has restricted the ability to walk, you must assess the patient's activity tolerance, tolerance to the upright position (orthostatic hypotension), strength, level of pain, coordination, and balance to determine the amount of assistance needed. Before getting the patient up, ensure the patient is wearing supportive, nonskid shoes.

Explain to the patient how far the patient should try to walk, who is going to help, when the walk will take place, and why walking is important. In addition, you and the patient should determine how much independence the patient can assume.

Check the walking environment to be sure that no obstacles are in the patient's path. Clear chairs, overbed tables, and wheelchairs out of the way so that the patient has ample room to walk safely. Before starting, establish rest points in case activity tolerance is less than estimated or the patient becomes dizzy. For example, a chair might be placed in the hall for the patient to rest, if needed. Provide support at the waist so that the patient's centre of gravity remains midline. This can be achieved by placing both hands at the patient's waist or using a gait belt. A gait belt is a belt that is placed around the lower rib cage to provide stability; it has handles that you can hold while the patient ambulates. The proper way to apply the belt is to keep two fingers between it and the patient's body. Tighten the belt until it has just enough room for your fingers. If the belt is too loose, it might slip upward and injure the patient's chest (particularly in women) or increase your risk of dropping the patient once weight is put on the belt. While walking, the patient should not lean to one side because this alters the centre of gravity, distorts balance, and increases the risk of falling. Walk to the side and slightly behind the patient (Figure 45-22).

A patient who at any point appears unsteady or complains of dizziness should be returned to a nearby bed or chair. If the patient has a syncopal (fainting) episode or begins to fall, assume a wide base of support with one foot in front of the other, providing enough support of the patient's body weight to prevent injury (Figure 45-23, A). Protecting the patient's head is the primary goal, but take care to avoid being injured yourself. To extend your front leg, move your back foot further away, and slide the patient against your forward leg to ease him or her to the floor (see Figure 45-23, B and 45-23, C). Practise this technique with a friend or classmate before attempting it in a clinical setting. When the patient attempts to ambulate again, proceed more slowly, monitoring for complaints of dizziness; also monitor the patient's blood pressure before, during, and after ambulation. Do not attempt to lift a patient manually from the floor, alone or with assistance. The best option is to allow the patient to get up without help, if possible, or to use mechanical lifting equipment.

Figure 45-22 When helping a patient walk, the nurse uses a gait belt and walks slightly behind the patient's side. **Source:** Sorrentino, S. A., Wilk, M. J., & Newmaster, R. (2009). *Mosby's Canadian textbook for the support worker* (2nd ed., p. 439, Fig. 24-22). Toronto: Elsevier.

Figure 45-23 A, Stand with feet apart to provide a broad base of support. B, Extend one leg and let patient slide against it to the floor. C, Bend knees to lower body as patient slides to the floor.

Figure 45-24 Patient using a standard walker.

If you do not have a lot of strength and are unable to ambulate a patient alone, you should request help. The two-nurse method helps distribute the patient's weight evenly. The two nurses stand on either side of the patient. Each nurse's near arm is around the patient's waist, and the other arm is around the inferior aspect of the patient's arm so that both nurses' hands are supporting the patient's axillae.

Using Assistive Devices for Walking. Patients recovering from a lengthy illness that required bed rest and whose mobility is impaired frequently require assistive devices to help them with ambulation. These devices include canes, walkers, and crutches. The patient and family must be educated in the use of these devices.

Walkers. Walkers are extremely light, moveable devices that are about waist high and made of metal tubing used to assist patients with walking. There are standard walkers that have four widely placed, sturdy, rubber-tipped legs (Figure 45-24). These are used by patients who need the most support when walking. The patient holds the handgrips on the upper bars, moves the walker forward, takes a step with the weaker or painful leg, and then takes a step with the unaffected leg. There are also two-wheeled walkers that have two wheels in the front and two sturdy legs in the back (Figure 45-25). These provide for support also, but allow the patient to move more quickly as the walker does not have to be lifted with each step. There are also walkers with four wheels, brakes, and a seat, often called rollators or rollator walkers (Figure 45-26). These walkers are used with patients who have mild balance problems.

Canes. Canes are lightweight, easily moveable devices made of wood or metal. They provide less support than a walker and are less stable. A person's cane length is equal to the distance between the floor and the crease at their wrist when they are standing tall with their arm straight down at their side. Two common types of canes are the single straight-legged cane and the quad cane. The single straight-legged cane is more common and is used to support and balance a patient with decreased leg strength. This cane should be kept on the stronger side of the body. For maximum support when walking, the patient places the cane forward 15 to 25 cm,

Figure 45-25 Patient using a two-wheeled walker.

Figure 45-26 Patient using a rollator walker.

keeping the body weight on both legs. The weaker leg is moved forward to the cane so that the body weight is divided between the cane and the stronger leg. The stronger leg is then advanced past the cane so that the weaker leg and body weight are supported by the cane and weaker leg. During walking, the patient continually repeats these three steps. The patient must be taught that two points of support, such as both feet or one foot and the cane, are present at all times.

The quad cane provides the most support and is used when partial or significant leg paralysis or some hemiplegia is present. The same three steps used with the straight-legged cane are used with the quad cane and need to be taught to the patient.

Crutches. Crutches are often needed to increase mobility. Begin crutch instruction with guidelines for safe use (Box 45-11). The use of crutches may be temporary, such as after ligament damage to the knee. A patient with paralysis of the

BOX 45-11 PATIENT TEACHING
Crutch Safety
Objective

- Patient will describe and demonstrate safe crutch walking.

Teaching Strategies

- Teach patient with axillary crutches about the dangers of pressure on the axillae, which occurs when leaning on the crutches to support body weight.
- Explain why the patient must use crutches that were measured for him or her.
- Show the patient how to routinely inspect crutch tips. Rubber tips should be securely attached to the crutches. When tips become worn out, they should be replaced. Rubber crutch tips increase surface friction and help prevent slipping.
- Explain that the crutch tips should remain dry. Water decreases surface friction and increases the risk of slipping.
- Explain that the patient should wear nonslip shoes and not wear an open gown or other long, flowing clothing to decrease the risk of falls.
- Show patient how to inspect the structure of the crutches.
- Cracks in a wooden crutch decrease its ability to support weight. Bends in aluminum crutches can alter body alignment.
- Provide patient with a list of medical supply companies in the community where repairs, new rubber tips, handgrips, and crutch pads can be obtained.
- Instruct patient to have spare crutches and spare tips readily available.

Evaluation

- Patient can describe principles of crutch safety.
- Patient correctly demonstrates proper use of crutches.

Figure 45-27 Double adjustable Lofstrand, or forearm, crutch.

Figure 45-28 Measuring crutch length.

lower extremities, by contrast, may need crutches permanently. A crutch is a wooden or metal staff. The two types of crutches are the double adjustable Lofstrand, or forearm, crutch (Figure 45-27) and the axillary wooden or metal crutch. The forearm crutch has a handgrip and a metal band that fits around the patient's forearm. The metal band and the handgrip are adjusted to fit the patient's height. The axillary crutch has a padded curved surface at the top, which fits under the axilla. A handgrip in the form of a crossbar is held at the level of the palms to support the body. It is important that crutches be measured for the appropriate length and that patients be taught to use their crutches safely, to achieve a stable gait, to ascend and descend stairs, and to rise from a sitting position.

Measuring for Crutches. The axillary crutch is the more common crutch used. Measurements include the patient's height, the angle of elbow flexion, and the distance between the crutch pad and the axilla. When crutches are fitted, the length of the crutch should be from three to four fingerwidths from the axilla to a point 15 cm lateral to the patient's heel (Hoeman, 2008; Figure 45-28).

The handgrips should be positioned so that the patient's body weight is not supported by the axillae. Pressure on the axillae increases risk to underlying nerves, which could result in partial paralysis of the arm. Correct position of the handgrips is determined with the patient upright, supporting weight by the handgrips with the elbows slightly flexed at 30 degrees.

Figure 45-29 Verifying correct distance between crutch pads and axilla.

When the height and placement of the handgrips have been determined, you should again verify that the distance between the crutch pad and the patient's axilla is three to four fingerwidths (Figure 45-29).

Crutch Gait. The **crutch gait** is assumed by alternately bearing weight on one or both legs and on the crutches. The

Figure 45-30 Tripod position, basic crutch stance.

gait selected by the physician is determined by assessing the patient's physical and functional abilities and the disease or injury that resulted in the need for crutches. This section summarizes the basic crutch stance and the four standard gaits: four-point alternating gait, three-point alternating gait, two-point gait, and swing-through gait.

The basic crutch stance is the tripod position, formed when the crutches are placed 15 cm in front of and 15 cm to the side of each foot (Figure 45-30). This position improves the patient's balance by providing a wider base of support. The body alignment of the patient in the tripod position is an erect head and neck, straight vertebrae, and extended hips and knees. The tripod position is assumed before crutch walking.

Three-point alternating, or three-point, gait requires the patient to bear all of the weight on one foot. In a three-point gait, weight is borne on both crutches and then on the unaffected leg, and the sequence is repeated (Figure 45-31). The affected leg does not touch the ground during the early phase of the three-point gait. Gradually, the patient progresses to touchdown and full weight bearing on the affected leg.

The two-point gait requires at least partial weight bearing on each foot (Figure 45-32). The patient moves a crutch at the same time as the opposing leg, so that the crutch movements are similar to arm motion during normal walking.

The swing-through, or swing-through gait, is frequently used by patients with paraplegia who wear weight-supporting braces on their legs. With weight placed on the supported legs, the patient places the crutches one stride in front and then swings to or through the crutches while they support the patient's weight.

Crutch Walking on Stairs. When ascending stairs on crutches, the patient usually uses a modified three-point gait (Figure 45-33). The patient stands at the bottom of the stairs and transfers body weight to the crutches. The unaffected leg is advanced between the crutches to the stairs. The patient then shifts weight from the crutches to the unaffected leg. Finally, the patient aligns both crutches on the stairs. This sequence is repeated until the patient reaches the top of the stairs.

To descend the stairs (Figure 45-34), a three-phase sequence is also used. The patient transfers body weight to the unaffected leg. The crutches are placed on the stairs, and the patient begins to transfer body weight to the crutches, moving the affected leg forward. Finally, the unaffected leg is moved to the stairs with the crutches. Again, the patient repeats the sequence until reaching the bottom of the stairs.

Figure 45-31 Three-point gait with weight borne on unaffected leg. Solid foot and crutch tips show weight bearing in each phase. (Read from bottom to top.)

Figure 45-32 Two-point gait with weight borne partially on each foot and each crutch advancing with opposing leg. Solid areas indicate leg and crutch tips bearing weight. (Read from bottom to top.)

Figure 45-33 Ascending stairs. A, Weight is placed on crutch. B, Weight is transferred from crutches to unaffected leg on stairs. C, Crutches are aligned with unaffected leg on stairs.

Figure 45-34 Descending stairs. A, Body weight is on unaffected leg. B, Body weight is transferred to crutches. C, Unaffected leg is aligned on stairs with crutches.

Because in most cases patients will need to use crutches for some time, they should be adequately taught to use crutches on stairs before discharge. This instruction applies to all crutch-dependent patients, not just those who have stairs in their homes.

Sitting in a Chair With Crutches. As with crutch walking and crutch walking up and down stairs, the procedure for sitting in a chair involves phases and requires the patient to transfer weight (Figure 45-35). First, the patient gets positioned at the centre front of the chair with the posterior aspect of the legs touching the chair. Then the patient holds both crutches in the hand opposite the affected leg. If both legs are affected, as with a patient with paraplegia who wears weight-supporting braces, the crutches are held in the hand on the patient's stronger side. With both crutches in one hand, the

patient supports body weight on the unaffected leg and the crutches. While still holding the crutches, the patient grasps the arm of the chair with the remaining hand and lowers his or her body into the chair. To stand, the procedure is reversed, and the patient, when fully erect, should assume the tripod position before beginning to walk.

◆Evaluation

Patient Care

To evaluate outcomes and response to nursing care, measure the effectiveness of all interventions. Compare the actual outcomes with the outcomes selected during planning. Evaluate specific interventions designed to promote body alignment, improve mobility, and protect the patient from the hazards of

Figure 45-35 Sitting in a chair. **A**, Both crutches are held by one hand. Patient transfers weight to crutches and unaffected leg. **B**, Patient grasps arm of chair with free hand and begins to lower herself into chair. **C**, Patient completely lowers herself into chair.

immobility. Also evaluate patient and family instruction to prevent future risks to body alignment and hazards of immobility (Figure 45-36). The evaluation enables you to determine whether new or revised therapies are required and if new nursing diagnoses have developed.

Patient Expectations

Patients who are immobile and dependent on others for some or all of their needs can become overly dependent or try to do too much themselves too early. Finding the balance between independence and dependence is a difficult task. Patients will want control over mobility that is personally satisfactory. For the patient who is completely dependent on others for care, control over how and when things are done may be very important. Do patients feel they are treated with dignity? Do caregivers treat them as adults? Are they given opportunities to make meaningful choices?

❖ KEY CONCEPTS

- Body mechanics are the coordinated efforts of the musculoskeletal and nervous systems as the person moves, lifts, bends, stands, sits, lies down, and completes daily activities.
- Balance is assisted through nervous system control by the cerebellum and inner ear.
- Range-of-motion (ROM) exercises include one or all of the body joints and can be active or passive.
- Body alignment is the condition of joints, tendons, ligaments, and muscles in various body positions.
- Balance is achieved when a wide base of support is present, the centre of gravity falls within the base of support, and a vertical line falls from the centre of gravity through the base of support.
- Developmental stages influence body alignment and mobility; the greatest impact of physiological changes on the musculoskeletal system is observed in children and older adults.
- The risk of disabilities related to immobilization depends on the extent and duration of immobilization and the patient's overall level of health.

Figure 45-36 Critical thinking model for immobility evaluation.

- Immobility may result from illness or trauma or may be prescribed for therapeutic reasons (bed rest).
- Immobility presents hazards in the physiological, psychological, and developmental dimensions.
- Use the nursing process and critical thinking synthesis to provide care for patients who are experiencing or are at risk for the adverse effects of impaired body alignment and immobility.
- After identifying nursing diagnoses, plan and implement interventions to prevent or minimize the hazards and complications of impaired body alignment and immobilization.
- Patients with weakness and impaired function of the nervous, skeletal, or muscular system often require nursing assistance to attain proper body alignment while in bed or sitting and to transfer from a bed to a chair.
- Positioning devices help patients maintain good body alignment while lying or sitting.
- Assistive devices to promote walking include canes, walkers, and crutches.

✦ CRITICAL THINKING EXERCISES

1. You are caring for a 57-year-old man who had bilateral total knee replacements for osteoarthritis two days ago. He is beginning to transfer to a chair with help. He is 45 kg overweight and has a history of deep vein thrombosis. He has compression stockings, continuous passive range of motion, and a saline lock. Make a list of potential nursing diagnoses.
2. When you are conducting a home visit for a 75-year-old woman, the patient's granddaughter runs in and says, "Did you show the nurse the sore on your leg that you got from falling yesterday?" What questions about mobility are important to ask the patient? How do you begin your assessment?
3. You are caring for a 68-year-old man who is immobilized after spinal cord trauma from a motor vehicle accident. What potential complications would you assess for in this patient?

✦ REVIEW QUESTIONS

1. A patient is unable to dorsiflex or evert the foot, a condition known as
 1. Kyphoscoliosis
 2. Footdrop
 3. Torticollis
 4. Kyphlordosis
2. A physiological risk associated with prolonged immobility is
 1. Decreased bone resorption
 2. Increased cardiac output
 3. Decreased muscle mass
 4. Increased metabolism
3. A patient has been on bed rest for several days. The patient stands and you note that the patient's systolic pressure drops 20 mm Hg. This is referred to as
 1. Orthostatic hypotension
 2. Rebound hypotension
 3. Positional hypotension
 4. Central venous hypotension
4. Elastic stockings help to prevent thrombus formation by
 1. Preventing varicose veins
 2. Preventing muscular atrophy
 3. Increasing venous return
 4. Ensuring joint mobility

5. The patient at greatest risk for developing adverse effects of immobility is a
 1. 3-year-old child with a fractured femur
 2. 48-year-old woman after a thyroidectomy
 3. 78-year-old man in traction for a broken hip
 4. 38-year-old woman undergoing a hysterectomy
6. A patient has been immobilized for five days because of extensive abdominal surgery. When getting this patient out of bed for the first time, a nursing diagnosis related to the safety of this patient would be
 1. Pain
 2. Impaired skin integrity
 3. Altered tissue perfusion
 4. Risk for activity intolerance
7. The following device allows the patient to pull with the upper extremities to raise the trunk off the bed, to assist in transfer from bed to wheelchair, or to perform upper arm exercises:
 1. Trapeze bar
 2. Trochanter roll
 3. Hand rolls
 4. Footboard
8. The patient in this position is lying chest down:
 1. Supine
 2. Prone
 3. Fowler's
 4. Lateral
9. When positioning a patient in the supported Fowler's position, you would place a small pillow under the patient's thighs to
 1. Decrease intracranial pressure
 2. Support the lumbar vertebrae
 3. Prevent occlusion of popliteal artery
 4. Prevent pressure of mattress on heel

✦ RECOMMENDED WEB SITES

Canadian Association of Rehabilitation Nurses (CARN): <http://www.carn.ca>

This Web page provides access to the CARN and includes information about membership, education events, and Canadian certification in rehabilitation nursing.

(American) Association of Rehabilitation Nurses: <http://www.rehabnurse.org/>

This Web page provides an extensive list of links to resources for nurses working with patients with actual or potential impairments or disabilities. It provides information about both prevention and treatment. Although the content has an American orientation, it is also useful to Canadian nurses.

Canadian Physical Activity Guidelines: <http://www.csep.ca/english/view.asp?x=804>

This Web page of the Canadian Society of Exercise Physiologists provides guides to physical activity for all age groups and includes a guideline specific to those with spinal cord injuries. These guides are a good source of consumer education on the benefits of activity.

Osteoporosis Canada: Health Professionals Resource Links: <http://www.osteoporosis.ca>

Osteoporosis Canada is a national organization that works toward educating and supporting individuals and communities in the prevention and treatment of osteoporosis. This site

provides numerous links to evidence-informed resources on osteoporosis.

The Registered Nurses' Association of Ontario (RNAO) Best Practice Guidelines: *Prevention of Falls and Injury in the Older Adult*: <http://www.rnao.org/Page.asp?PageID=924&ContentID=810>

The RNAO has developed a series of practice guidelines based on the consensus of nurse experts across a variety of practice,

academic, and research agencies. This site provides information on patient participation in ADLs, cognition, continence, strength, gait, and balance in relation to the risk for falls.

Review Question Answers

1, 2, 2, 3, 3, 1, 4, 3, 5, 3, 6, 4, 7, 1, 8, 2, 9, 3

Rationales for the Review Questions appear at the end of the book.

Skin Integrity and Wound Care

Written by Rosemary Kohr, RN, MScN, PhD, Tertiary Care Nurse Practitioner Certificate (UWO, 1998)

Based on the original chapter by Janice Colwell, RN, MS, CWOCN, FAAN

objectives

Mastery of content in this chapter will enable you to:

- Describe the key terms listed.
- Discuss the risk factors that contribute to pressure ulcer formation.
- Recognize the stages of pressure ulcers.
- Describe the etiology and key components of venous, arterial, diabetic, and malignant wounds.
- Discuss the normal process of wound healing.
- Describe the differences between wounds that heal by primary and secondary intention.
- Describe the complications of wound healing.
- Explain the factors that impede or promote wound healing.
- Describe the differences in nursing care for acute and chronic wounds.
- Describe the types of dressings appropriate for moist wound healing.
- Complete an assessment for a patient with impaired skin integrity.
- List nursing diagnoses associated with impaired skin integrity.
- Develop a nursing care plan for a patient with impaired skin integrity.
- List appropriate nursing interventions for a patient with impaired skin integrity.
- State evaluation criteria for a patient with impaired skin integrity.

Skin, the body's largest organ, constitutes 15% of the total adult body weight (Wysocki, 2007). It protects against disease-causing organisms; senses pain, temperature, and touch; and synthesizes vitamin D. Injury to the skin poses risks to safety and triggers a complex healing response.

As a nurse, one of your most important responsibilities is to monitor skin integrity and prevent skin breakdown. Understanding normal wound healing helps in planning, implementing, and assessing interventions that maintain skin integrity and optimize wound healing.

Figure 46-1 Layers of skin. **Source:** Pires, M., & Muller, A. (1991). Detection and management of early tissue pressure indicators: A pictorial essay. *Progressions*, 3(3), 3.

Scientific Knowledge Base

Skin

The skin has two layers: the epidermis and the dermis (Figure 46-1). These two layers are separated by a membrane, often referred to as the dermal–epidermal junction. The epidermis, or top layer, also consists of several layers. The stratum corneum is the thin, outermost layer of the epidermis, consisting of flattened, keratinized cells. The cells originate from the innermost epidermal (or basal) layer. These cells divide, proliferate, and migrate toward the epidermal surface.

After cells reach the stratum corneum, they flatten and die. This constant movement ensures replacement of surface cells sloughed during normal desquamation or shedding. The stratum corneum protects underlying cells and tissues from dehydration and prevents the entrance of certain chemical agents. The stratum corneum allows the evaporation of water from the skin and permits the absorption of certain topical medications.

The dermis, the inner layer of the skin, provides tensile strength, mechanical support, and protection to the underlying muscles, bones, and organs. It differs from the epidermis in that it contains mostly connective tissue and few skin cells. Collagen (a tough, fibrous protein), blood vessels, and nerves are in the dermal layer. Fibroblasts, which are responsible for collagen formation, are the only distinctive cell type within the dermis.

Understanding skin structure helps you to maintain skin integrity and promote wound healing. Intact skin protects the patient from chemical and mechanical injuries. When the skin is injured, the epidermis functions to resurface the wound and restore the barrier against invading organisms while the dermis responds to restore the structural integrity (collagen) and the physical properties of the skin. Age alters skin characteristics and makes skin more vulnerable to damage. Box 46-1 provides a summary of the changes in aging skin.

Pressure Ulcers

Pressure ulcer, *pressure sore*, *decubitus ulcer*, and *bedsore* are terms used to describe impaired skin integrity related to unrelieved, prolonged pressure. The most current terminology is *pressure ulcer*, which is consistent with the recommendations of the pressure ulcer guidelines developed by the Registered Nurses' Association of Ontario (RNAO) (RNAO, 2007). A **pressure ulcer** is localized injury to skin and underlying tissue, usually over a bony prominence, as a result of pressure, or in combination with shear and/or friction (Figure 46-2).

Pressure ulcers have a high prevalence rate in all health care settings. It is estimated that one individual in four within the

* BOX 46-1 FOCUS ON OLDER ADULTS

Skin-Associated Issues

- Age-related changes, such as reduced skin elasticity, decreased collagen, and thinning of underlying muscle and tissues, cause the older adult's skin to be easily torn via mechanical trauma, especially shearing forces (Wysocki, 2007).
- Concomitant medical conditions and polypharmacy, common in the older adult, interfere with wound healing.
- The attachment between the epidermis and dermis becomes flattened in older adults, allowing skin to be easily torn from mechanical trauma (e.g., tape removal).
- Aging causes a diminished inflammatory response, resulting in slow epithelialization and wound healing (Doughty & Sparks-Defries, 2007).
- The hypodermis decreases in size with age. Older patients have little subcutaneous padding over bony prominences, so they are more prone to skin breakdown (Wysocki, 2007).
- Reduced nutritional intake, commonly seen in older adults, increases the risk of pressure ulcer development and impaired wound healing (Posthauer & Thomas, 2004).

Canadian health care system has some issue with skin integrity (Woodbury & Houghton, 2004). The prevalence rate in acute care settings is 25%; nonacute care settings (including long-term care facilities), 30%; and community care and home care settings, 15% (Woodbury & Houghton, 2004).

The impact of pressure ulcers and other chronic wounds on quality of life is significant, as normal activities may be restricted because of pain, odour, or treatments. Costs associated with chronic wound care can substantially increase the burden on the health care system. It has been estimated that in the United States, an increase of 50% of nursing time along with treatments can cost from \$10,000 to \$86,000 (US\$; in Canadian currency, \$12,300 to \$105,800) (Clarke et al., 2005).

Thus, it is essential that attention be paid to the causes of pressure ulcers as well as to the healing process of wounds. The focus of this text is on pressure ulcer prevention and treatment options, but other chronic wounds, such as diabetic, arterial, venous, and malignant wounds, will be briefly discussed and are important for you to recognize and treat. Additional resources are readily available on Web sites for the Canadian Association of Wound Care (CAWC), the Canadian Association of Enterostomal Therapists (CAET), and the Registered Nurses' Association of Ontario (RNAO), which has produced a large number of evidence-informed best practice guidelines for pressure ulcers, venous leg ulcers, diabetic foot ulcers, continence, and constipation, among others. These and other resources are provided for you at the end of this chapter.

Pathogenesis of Pressure Ulcers. Pressure is the major element in the cause of pressure ulcers. Three pressure-related factors contribute to pressure ulcer development: (1) pressure intensity, (2) pressure duration, and (3) tissue tolerance.

Pressure Intensity. A classic research study identified capillary closing pressure as the minimal amount of pressure required to collapse a capillary (e.g., when the pressure exceeds the normal capillary pressure range of 15 to 32 mm Hg) (Burton & Yamada, 1951). Therefore, if pressure applied over a capillary exceeds the normal capillary pressure and the vessel is

Figure 46-2 A, Bony prominences most frequently underlying pressure ulcers. B, Common pressure ulcer sites. **Source:** Adapted from Trelease, C. C. (1988). Developing standards for wound care. *Ostomy/Wound Management*, 20, 46.

Figure 46-3 A, Reactive hyperemia. B, Blanching erythema: blanches with fingertip pressure.

occluded for a prolonged period of time, **tissue ischemia**, or reduction in blood flow, can occur. If the patient has decreased sensation and thus does not have the cue of discomfort to prompt shifting (off-loading) pressure, tissue death may result. The clinical presentation of obstructed blood flow occurs when you evaluate areas of pressure. After a period of tissue ischemia, if pressure is relieved and blood flow returns, the skin turns red. The effect of this redness is vasodilatation (blood vessel expansion), called **hyperemia** (redness) (Figure 46-3, A). Evaluate the area of hyperemia by pressing a finger over the affected area. If the area blanches (turns lighter in colour) (Figure 46-3, B) and the redness returns when you remove your finger, hyperemia is transient and is an attempt to overcome the ischemic episode; thus, it is called **blanching hyperemia** (Pieper, 2007).

If, however, the erythematous area does not blanch (non-blanching erythema) (Figure 46-4) when you apply pressure, deep tissue damage is probable.

Blanching occurs when the normal red tones of light-skinned patients are absent. Blanching does not occur in

patients with darkly pigmented skin. The Task Force on the Implications for Darkly Pigmented Intact Skin in the Prediction and Prevention of Pressure Ulcers (Bennett, 1995) defined **darkly pigmented skin** as skin that “remains unchanged (does not blanch) when pressure is applied over a bony prominence, irrespective of the patient’s race or ethnicity.” Characteristics of intact dark skin that will alert you to the potential for pressure ulcers are found in Box 46-2.

Pressure Duration. Two considerations are related to duration of pressure. Low pressures over a prolonged time period and high-intensity pressure over a short period of time both cause tissue damage. Extended pressure occludes blood flow and nutrients and contributes to cell death (Pieper, 2007). Clinical implications of pressure duration include evaluating the amount of pressure (check the skin for reactive hyperemia) and the amount of time that a patient tolerates pressure (check to be sure that after removing pressure, the affected area blanches).

Tissue Tolerance. The ability of tissue to endure pressure depends on the integrity of both the tissue and supporting

Figure 46-4 A, Reactive hyperemia. B and C, In nonblanching erythema, the area is much darker than the surrounding skin and does not blanch with fingertip pressure. **Source:** Pires, M., & Muller, A. (1991). Detection and management of early tissue pressure indicators: A pictorial essay. *Progressions*, 3(3), 3.

structures. The extrinsic factors of shear, friction, and moisture affect the ability of the skin to tolerate pressure: the greater the degree to which these factors are present, the more susceptible the skin will be to damage from pressure. Another factor related to tissue tolerance pertains to the ability of the underlying skin structures (blood vessels, collagen) to assist in redistributing pressure. Systemic factors such as poor nutrition, age, and low blood pressure affect tissue tolerance to externally applied pressure.

► BOX 46-2

Characteristics of Dark Skin at Risk of Skin Breakdown

A natural or halogen light source is best for assessing skin. Avoid fluorescent light sources because they cast a bluish hue, making accurate assessment difficult.

Colour

Appears darker than surrounding skin
Has purplish or bluish hue

Temperature

Initial warmth when compared with surrounding skin
Later coolness as tissue is devitalized

Touch

Indurated
Edema
Soft, boggy

Appearance

Taut
Shiny
Scaly

Nursing Knowledge Base

Prediction and Prevention of Pressure Ulcers

A major aspect of nursing care is the maintenance of skin integrity. Consistent, planned skin care interventions are critical to ensuring high-quality care. You need to take every opportunity to observe and assess your patients' skin for impaired skin integrity.

Risk Factors for Pressure Ulcer Development.

A variety of factors predisposes a patient to pressure ulcer formation. These factors are often directly related to disease, such as a decreased level of consciousness, the after-effects of trauma, or the presence of a cast, or are secondary to an illness, such as decreased sensation after a cerebrovascular accident.

The use of a pressure ulcer risk assessment tool, such as the Braden Risk Assessment Tool (described later in Table 46-2), provides an initial assessment to determine appropriate interventions and ongoing regular assessment to evaluate skin status and treatment efficacy.

Impaired Sensory Perception. Patients with altered sensory perception of pain and pressure are at more risk of impaired skin integrity than are patients with normal sensation. Patients with impaired sensory perception of pain and pressure may not feel increased, prolonged pressure or pain and are at high risk of developing pressure ulcers (Skill 46-1).

Impaired Mobility. Patients unable to independently change positions are at risk of pressure ulcer development. For example, patients with spinal cord injuries have decreased or absent motor and sensory perception and are unable to reposition themselves.

Alteration in Level of Consciousness. Patients who are confused or disoriented or with changing levels of consciousness may not be able to understand the sensation of pressure and respond by repositioning independently. As well, they may not be able to communicate discomfort or pain. Patients in a coma cannot perceive pressure and are unable to move voluntarily to relieve pressure.

Shear. Shear is the force exerted parallel to the skin and results from both gravity pushing down on the body and

► SKILL 46-1 Assessment for Risk of Pressure Ulcer Development

Delegation Considerations

Assessment of patients for risk of pressure ulcers should not be delegated to unregulated care providers (UCPs); however, prevention strategies should be included in their work plan. Check with your institution's policy in this regard.

Prevention

- Document changes to patient's skin, such as redness, blistering, abrasions, or cuts.
- Keep patient's skin dry: cleanse well after incontinence (urine or stool) or exposure to other body fluids.
- Reposition patient according to frequency established in nursing care plan or agency policy.
- Avoid trauma to patient's skin from tape, pressure, friction, or shear.

Equipment

- Use a risk assessment tool: Braden Scale (used in this skill) or other tool, according to agency policy.
- Documentation record

Procedure

STEPS

1. Identify at-risk individuals needing prevention and specific risk factors.
 - A. Use a validated risk assessment tool (e.g., the Braden Scale).
 - B. Assess the patient on admission to hospital, long-term care facility, home care program, or other health care facility.
 - C. Inspect the condition of the patient's skin at least once a day (see Box 46-4) and examine all bony prominences, noting skin integrity. (Check agency policy for reassessment and reassess at periodic intervals.) If redness or discoloration is noted, palpate area of redness for blanchable erythema.

RATIONALE

- Identification determines factors that increase the patient's risk of developing pressure ulcers (Braden, 2001).
- Consistent, reliable, comparable assessments are ensured (AHCPR, 1992a, 1992b; NPUAP, 2007a, 2007b; RNAO, 2007).
- A baseline assessment is provided.
- Routine skin assessments will identify changes in patient's risk of pressure ulcers.
- Nonblanchable erythema or discoloration in the patient's skin may be an early indicator of skin injury (Pieper, 2007).

Critical Decision Point: In dark-skinned patients, the discoloration appears as a deepening of the normal colour (see Box 46-2). Darkly pigmented skin does not always show direct changes in colour (Bennett, 1995; NPUAP, 1998).

- D. Observe all assistive devices, such as braces or casts, and medical equipment, such as nasogastric and enteral tubes and catheters, for pressure points.
2. Determine patient's ability to respond meaningfully to pressure-related discomfort (sensory perception).
 - Presence of medical equipment may cause pressure and skin breakdown in sensitive regions, such as nostrils, ears, or other bony prominences.
 - Patients with completely, very, or slightly limited ability to respond to pressure-related discomfort cannot communicate discomfort, will have a limited ability to feel pain, and, thus, risk developing pressure ulcers.
 3. Assess the degree to which patient's skin is exposed to moisture.
 - Exposure to excessive moisture increases the risk of skin breakdown due to changes in skin pH and maceration of skin.
 4. Evaluate the patient's activity level.
 - A. Determine patient's ability to change and control body position (mobility).
 - B. Determine patient's preferred positions.
 - The patient who is bedfast, chairfast, or only walks occasionally limits repositioning and pressure off-loading due to physical inactivity.
 - Potential for friction and shear injury increases when the patient is completely dependent on others for position change.
 - Habitual positioning (e.g., lying on one side or the other) may result in skin breakdown as the patient may resist repositioning to different areas.
 - A patient who never eats a complete meal, rarely eats a complete meal, or has limited fluid intake is at risk of skin breakdown.
 5. Assess patient's usual food and fluid intake pattern (nutrition and hydration).
 - A. Review weight pattern and nutritional laboratory values.
 - B. Complete a fluid intake assessment.
 - Decreased nutritional status is linked with pressure ulcer formation and poor wound healing (AHCPR, 1994; RNAO, 2007).
 - Fluid imbalance, either dehydration or edema, can increase the patient's risk of pressure ulcers.
 6. Evaluate the presence of friction and shear.
 - The patient who has spastic limbs, requires maximum assistance in moving, or slides against sheets when moved is at an increased risk of skin damage.
 7. Document the risk assessment on admission, on a regular basis according to institutional policy, and if any change in status occurs (Sibbald, Orsted, et al., 2006).
 - The documentation provides a baseline to track risk of development of pressure ulcers and allow planning of interventions.

► SKILL 46-1 Assessment for Risk of Pressure Ulcer Development—cont'd

- A. Observe the Braden Scale scores: as they become lower, predicted risk becomes higher.
Existing skin breakdown increases the risk by one level.
- B. Link the risk assessment to preventive protocols.
- C. Institute mild-risk interventions (score of 15–16). Plan of care should include frequent turning; maximum remobilization; off-load heel pressure; use of pressure-reducing support surface; manage moisture, nutrition, and friction and shear.
- D. Institute moderate-risk interventions (score of 13–14). Plan of care should include interventions for mild risk (step 7c), as well as use of foam wedges to position the patient in the 30-degree lateral position.
- E. Institute high-risk interventions (score of 10–12). Plan of care should include interventions for moderate risk (step 7d), as well as instructions to turn the patient with small shifts in weight.
- F. Institute very high-risk interventions (score <10). Plan of care should include interventions for high risk (step 7e) as well as use of a pressure-relieving surface, which still requires frequent repositioning of patient.
- 8. Provide education to patient and family regarding pressure ulcer risk.
- 9. Evaluate measures to reduce pressure ulcer development.
 - A. Observe patient's skin for areas at risk.
 - B. Observe tolerance of patient for positioning.
 - C. Monitor the success of a toileting program or other measures to reduce the frequency of incontinence of urine or stool.
 - D. Evaluate laboratory nutrition values.
- Scores:
 - 15–16, mild risk
 - 13–14, moderate risk
 - 10–12, high risk
 - <10, very high risk
- Existing skin breakdown indicates risk factors are already present and require attention.
- Prevention protocols will target problem areas to assist in prevention of skin breakdown (Braden, 2001).
- The risk of skin breakdown is decreased.
- The increased risk of skin breakdown is decreased with appropriate interventions.
- The factors that contribute to skin breakdown are identified, and appropriate interventions are planned.
- Plan interventions to decrease the effects of immobility, decreased sensory perception, moisture, friction, shear, decreased activity, and nutritional issues in a high-risk individual.
- Patient and family understand and participate as much as possible in the interventions designed to reduce pressure ulcer risk.
- Evaluation on a regular basis provides opportunity to assess and adjust interventions.
- Patient's response to risk-reduction interventions is determined over time.
- Frequent change in position further reduces patient's risk of pressure ulcer development.
- Avoiding moisture from urine or stool on patient's skin reduces risk of skin breakdown.
- Value of nutritional supplements in improving nutritional status is determined.

Unexpected Outcomes

No blanching when skin is firmly pressed, purple discoloration, or significant colour change

Related Interventions

- Reassess frequency of turning schedule.
- Implement agency's skin care protocols.
- Consider support surface to reduce pressure ulcer risk.

Recording and Reporting

- Record patient's risk score and sub-scores.
- Record appearance of skin (at pressure points, etc).
- Describe position, turning intervals, pressure-relieving devices, and other prevention strategies.
- Report any need for additional consultations (e.g., wound care specialist or dietitian) for the high-risk patient.

Home Care Considerations

- Instruct the caregiver to use the 30-degree lateral position. This position reduces pressure over the trochanter.
- Pressure-relief manoeuvres need to be individualized for patient needs and the home environment. Provide the family with resources to access equipment.

resistance (friction) between the patient and a surface (Pieper, 2007). For example, shear force occurs when the head of the bed is elevated and the skeleton starts to slide but the skin is fixed because of friction with the bed (Figure 46-5). In addition, shear force occurs when you transfer a patient from the bed to a stretcher and the patient's skin is pulled across the bed. When shear is present, the skin and subcutaneous layers

adhere to the surface of the bed, while layers of muscle and the bones slide in the direction of body movement. The underlying tissue capillaries are stretched and angulated by the shear force. As a result, necrosis occurs deep within the tissue layers, causing undermining of the dermis. Heels are particularly vulnerable to injury from shear as patients are often repositioned in bed without the heels being supported.

Friction. The force of two surfaces moving across one another, such as the mechanical force exerted when skin is dragged across a coarse surface such as bed linens, is called **friction** (Wound, Ostomy, and Continence Nurses [WOCN], 2010). Unlike shear injuries, friction injuries affect the epidermis, or top layer of the skin. The denuded skin appears red and painful and is sometimes referred to as a “sheet burn.” A friction injury occurs in a patient who is dragged over the bed surface instead of being lifted slightly during position changes.

Moisture. The presence and duration of moisture on the skin increases the risk of ulcer formation. Moisture reduces the skin’s resistance to other physical factors such as pressure and shear force. Prolonged moisture softens skin, which makes it

more susceptible to damage. Immobilized patients, who are unable to take care of their own hygiene needs, depend on you to keep their skin dry and intact. Skin moisture originates from wound drainage, excessive perspiration, and fecal or urinary incontinence.

Nutrition. Adequate nutritional intake is essential for not only wound healing but also wound prevention (Skipper, 2010). In particular, high-protein oral nutritional supplementation is necessary in patients whose prealbumin or albumin, hemoglobin, and serum zinc stores are low (RNAO, 2011).

For patients weakened or debilitated by illness, nutritional therapy is especially important. A patient who has undergone surgery (see Chapter 48) and is well nourished still requires at least 1500 kcal/day for nutritional maintenance. Alternatives such as enteral feedings and parenteral nutrition (see Chapter 42) are available for patients unable to maintain normal food intake.

Normal wound healing requires proper nutrition (Table 46-1). Deficiencies in any of the nutrients result in impaired or delayed healing (Stotts, 2007a). Physiological processes of wound healing depend on availability of protein, vitamins (especially A and C), and trace minerals: zinc and copper. **Collagen** is a protein formed from amino acids acquired by fibroblasts from protein ingested in food. Vitamin C is necessary for the synthesis of collagen, and vitamin A reduces the negative effects of steroids on wound healing. Trace elements such as zinc (used for epithelialization and collagen synthesis) and copper (for collagen fibre linking) are also necessary.

Figure 46-5 Sketch of shear force exerted against the sacral area.

► TABLE 46-1 Role of Selected Nutrients in Wound Healing

Nutrient	Role in Healing	Recommendations	Sources
Calories	Fuel for cell energy “protein protection”	35–40 kcal/kg/day, or enough to maintain positive nitrogen balance	
Protein	Fibroplasia, angiogenesis, collagen formation, and wound remodelling, immune function	1.0–1.5 g/kg/day, or enough to maintain positive nitrogen balance	Poultry, fish, eggs, beef
Vitamin C (ascorbic acid)	Collagen synthesis, capillary wall integrity, fibroblast function, immunological function, antioxidant	100–1000 mg/day Need long time before clinical scurvy from vitamin C deficiency develops Low toxicity	Citrus fruits, tomatoes, potatoes, fortified fruit juices
Vitamin A	Epithelialization, wound closure, inflammatory response, angiogenesis, collagen formation Can reverse steroid effects on skin and delayed healing	1600–2000 retinol equivalents per day Supplement if deficient 20,000 units × 10 days	Green leafy vegetables (spinach), broccoli, carrots, sweet potatoes, liver
Vitamin E	No known role in wound healing, antioxidant	None	Fish, oysters, liver, dark meat, eggs, legumes
Zinc	Collagen formation, protein synthesis, cell membrane and host defences	15–30 mg Correct deficiencies No improvement in wound healing with supplementation unless zinc deficient Use with caution: large doses can be toxic May inhibit copper metabolism and impair immune function	Vegetables, meats, legumes
Fluid	Essential fluid environment for all cell function	30–35 mL/kg/day Increase by another 10–15 mL/kg if patient is on an air-fluidized bed	Use noncaffeine, nonalcoholic fluids without sugar Water is best: 6–8 glasses/day

Adapted from Ayello, E. A., Thomas, D. R., & Litchford, M. A. (1999). Nutritional aspects of wound healing. *Home Health Nurse*, 17(11), 719; and Stotts, N. A. (2007). Nutritional assessment and support. In R. A. Bryant & D. P. Nix (Eds.), *Acute and chronic wounds: Current management concepts* (3rd ed.). St Louis, MO: Mosby.

Calories provide the energy to support wound healing. Protein needs, especially, are increased. A balanced nutrient intake is critical for wound healing, including protein, fat, carbohydrates, vitamins, and minerals. Serum proteins are biochemical indicators of malnutrition (Stotts, 2007a). Although serum albumin is the most frequently measured of these laboratory parameters, it is not sensitive to rapid changes in nutritional status. The best measure of nutritional status is pre-albumin because it reflects not only what the patient has ingested but also what the body has absorbed, digested, and metabolized (Stotts, 2007a).

Tissue Perfusion. Oxygen fuels the cellular functions essential to the healing process; therefore, the ability to perfuse the tissues with adequate amounts of oxygenated blood is critical to wound healing (Doughty & Sparks-Defriese, 2007). Patients with shock or peripheral vascular diseases, such as diabetes, are at risk of poor tissue perfusion due to poor circulation. Oxygen requirements depend on the phase of wound healing; for instance, chronic tissue hypoxia is associated with impaired collagen synthesis and reduced tissue resistance to infection.

Infection. Wound infection prolongs the inflammatory phase, delays collagen synthesis, prevents epithelialization, and increases the production of proinflammatory cytokines, which leads to additional tissue destruction (Stotts, 2007b). Indications that a wound infection is present are the presence of pus; a change in odour, volume, or the character of wound drainage; redness in the surrounding tissue; fever; or pain (Box 46-3).

Pain. Uncontrolled pain can affect the patient's ability to tolerate movement and can decrease tissue perfusion because of rapid, shallow breathing and tensed muscles. In addition, the patient's appetite may be diminished because of nausea from pain, and if the restorative powers of sleep are not accessible, the individual may feel hopeless and depressed from the unrelenting nature of both the wound and the persistent pain (Kohr & Gibson, 2008).

Age. Physiological changes occur with aging. These changes will affect the healing trajectory of a wound. For example, decrease in the functioning of macrophages leads to a delayed inflammatory response, delayed collagen synthesis, and slower epithelialization.

► BOX 46-3 Classic Signs of Wound Infection

- Pain and tenderness at the wound site
- Erythema (reddening of the surrounding tissue)
- Edema (swelling), **induration** (increased firmness of the tissue)
- Inflammation of wound edges
- Purulent discharge
- Warmth in surrounding tissue
- Fever, chills
- Foul odour
- Elevated white blood cell count
- Delayed healing

Chronic Wounds

The above signs and symptoms as well as the following:

- Increased exudates
- Bright red discolouration of granulation tissue
- New areas of slough or breakdown on the wound surface
- Undermining (dead space under the edges of the wound)

Psychosocial Impact of Wounds. The patient's psychological response to any wound is part of your assessment. Body-image changes often impose a great stress on the patient's adaptive mechanisms. In addition, body-image changes influence self-concept (see Chapter 25) and sexuality (see Chapter 26). Make sure the patient's personal and social resources for adaptation are a part of the assessment. Factors that affect the patient's perception of the wound include the presence of scars, drains (drains are often necessary for weeks or even months after certain procedures), odour from drainage, and temporary or permanent prosthetic devices.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgement means you need to anticipate the information necessary, analyze the data, and make decisions regarding patient care. Critical thinking is always changing. During assessment, consider all elements that build toward making appropriate nursing diagnoses (Figure 46-6).

When caring for patients who have impaired skin integrity and chronic wounds, you must integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients to understand the risks to skin integrity and wound healing. Knowledge of normal musculoskeletal physiology, the pathogenesis of pressure ulcers, normal wound healing, and the pathophysiology of underlying diseases provides you with a scientific basis for care. The CAWC (2006) and the RNAO (2011) provide evidence-derived guidelines for assessment of the risk of impaired skin integrity, prevention measures, and interventions to promote wound healing, as well as other standards of practice that you should use in planning care. Past experience with patients at risk of impaired skin integrity or with patients with wounds increases the experiential knowledge base helping you to identify interventions.

Finally, you need to ensure that you remain attentive during assessment to obtain comprehensive and correct assessment data. As identified previously, a *continuum* exists to wound healing that implies change over time. You need to be aware that the patient and the skin or wound condition will not remain static, so you should reassess on a regular basis and adjust your plan of care accordingly. Knowledge and experience regarding wound healing will assist you in taking advantage of all the available and appropriate treatment options.

Assessment for tissue pressure damage involves visual and tactile inspection of the skin. Your baseline assessment will determine the patient's normal skin characteristics and any potential or actual areas of breakdown. You need to take into account the specific characteristics of the patient's skin, including pigmentation, effects of aging or medication, etc. (Bennett, 1995; Henderson et al., 1997). Assessment characteristics of darkly pigmented skin appear in Boxes 46-2 and 46-5.

Pay particular attention to areas located over bony prominences or under casts, traction, splints, braces, collars, or other orthopedic devices. The frequency of pressure checks depends on the schedule of appliance application and the skin's response to the external pressure (Figure 46-7).

When you note hyperemia, document the location, size, and colour and reassess the area after one hour (Figure 46-8, A). When you suspect abnormal reactive hyperemia, outline the affected area with a marker to make reassessment easier. These

Knowledge

- Pathogenesis of pressure ulcers
- Factors contributing to pressure ulcer formation or poor wound healing
- Factors contributing to wound healing
- Impact of underlying disease process on skin integrity
- Impact of medication on skin integrity and wound healing

Experience

- Caring for patients with impaired skin integrity or wounds
- Observation of normal wound healing

Assessment

- Identify the patient's risk for developing impaired skin integrity
- Identify signs and symptoms associated with impaired skin integrity or poor wound healing
- Examine patient's skin for actual impairment in skin integrity

Standards

- Apply intellectual standards of accuracy, relevance, completeness, and precision when obtaining health history regarding skin integrity and wound management
- Knowledge of AHRQ (AHCPR, 1992a) standards for prevention of pressure ulcers
- Knowledge of standards for assessment of risk for impaired skin integrity and prevention

Qualities

- Use discipline to obtain complete and correct assessment data regarding patient's skin or wound integrity
- Demonstrate responsibility for collecting appropriate specimens for diagnostic and laboratory tests related to wound management

Figure 46-6 Critical thinking for skin integrity and wound care assessment.

signs are early indicators of impaired skin integrity, but damage to the underlying tissue is sometimes more progressive (Figure 46-8, B). Palpation with your fingertips will help you assess and identify induration or other damage to skin and underlying tissues.

Gently palpate the reddened tissue, observing for blanching as normal skin tones return in patients with light-toned skin. In addition, palpate for induration, noting size in millimetres or centimetres of the induration around the injured area. Also note changes in the temperature of the surrounding skin and tissues.

Use visual and tactile inspection over the body areas most frequently at risk of pressure ulcer development (see Figure 46-2).

Nursing Process

◆ Assessment

Skin integrity is subject to change over time. Baseline and continual assessment data support critical information about

Figure 46-7 A pressure ulcer on the heel caused by pressure exerted by the mattress.

Figure 46-8 A, Hyperemia on ischial tuberosity. B, Ulcer. **Source:** Pires, M., & Muller, A. (1991). Decision and management of early tissue pressure indicators: A pictorial essay. *Progressions*, 3(3), 3.

► BOX 46-4 Nursing Assessment Questions

Skin Integrity

Sensation

- Do you have any loss of feeling in your feet or legs or anywhere else?
- Do you feel more (or less) sensitive to heat or cold?

Mobility

- Do you have any physical conditions, injury, or paralysis that limits your mobility?
- Can you easily change your position?
- Is it painful to move?

Continence

- Do you have any problems with urine or bowel continence?
- Do you need help when you use the toilet?
- How often do you need to use the toilet? During the day? During the night?

Presence of a Wound

- How did this wound happen?
- When did the wound occur?
- When did you last receive a tetanus shot?
- What happened to this wound since it occurred? Is it getting better? Or worse?
- What treatments, activities, or care have slowed or helped the wound healing process? Are there other things we could be doing to improve things?
- Is the wound painful? If so, can you describe the pain (burning, stabbing, sharp, dull, etc.) or is it itchy? What have you been doing to manage this? Is it working?
- What would you like, in terms of the goal for yourself, in relation to this wound and its healing?

the patient's skin integrity and the increased risk of pressure ulcer development. The specific factors, such as continence status or mobility, help focus your assessment (Box 46-4).

Skin

You should ensure that ongoing assessment occurs to guard against skin breakdown, and you should treat any tears or ulcers promptly (Box 46-5). The neurologically impaired patient, the chronically ill patient in long-term care, the patient with diminished mental status, and patients in the intensive care unit (ICU) or oncology, hospice, or orthopedic departments all have an increased potential of developing pressure ulcers.

Risk Assessment

By identifying and promptly treating at-risk patients, you can spare patients with little risk of pressure ulcer development the unnecessary and sometimes costly preventive treatments and related risks of complications. Prevention and treatment of pressure ulcers are major nursing priorities, no matter what the health care setting. Evidence exists that a program of prevention guided by consistent risk assessment simultaneously reduces the institutional incidence of pressure ulcers by as much as 60% and decreases the costs of prevention at the same time (Braden, 2001). The Braden Pressure Ulcer Risk Assessment Scale has been identified by the CAWC and the RNAO Best Practice Guidelines as a reliable and valid risk assessment

* BOX 46-5 CULTURAL ASPECTS OF CARE

Skin Colour Impact

Your ability to detect cyanosis and other changes in skin colour in patients is an important clinical skill. However, this detection becomes a challenge in dark-skinned patients. Cyanosis is “a slightly bluish greyish slate-like or dark purple discolouration of the skin due to the presence of at least 5 grams of reduced hemoglobin in arterial blood.” Colour differentiation of cyanosis varies according to skin pigmentation. In dark-skinned patients, you need to know the individual's baseline skin tone. You should not confuse the normal hyperpigmentation of Mongolian spots that are seen on the sacrum of African, Native American, and Asian patients as cyanosis. Observe the patient's skin in nonglare daylight. The Gaskin's Nursing Assessment of Skin Colour (GNASC) is a useful assessment tool for identifying changes in skin colour that increase the patient's risk of pressure ulcers.

Implications for Practice

- Cyanosis is difficult but possible to detect in the dark-skinned patient.
- Be aware of situations that produce changes in skin tone, such as inadequate lighting.
- Examine body sites with the least melanin, such as under the arm, for underlying colour identification.
- Evaluate pigmented skin for colour-specific changes in skin tone.

Sources: Adapted from Gaskin, F. C. (1986). Detection of cyanosis in the person with dark skin. *Journal of National Black Nurses' Association*, 1, 52; and Henderson, C. T., Ayello, E. A., Sussman, C., Leiby, D. M., Bennet, M. A., Dungog, E. F., Sprigle, S., & Woodruff, L. (1997). Draft definition of stage I pressure ulcers: Inclusion of persons with darkly pigmented skin. *Advances in Wound Care*, 10(5), 16.

tool across all health care sectors and is the most commonly used (RNAO, 2011; Keast et al., 2006). However, an assessment tool is exactly that, a tool to assist you in planning intervention strategies and evaluation of your patient's skin on an ongoing basis. No assessment tool can replace your clinical judgement as a nurse (RNAO, 2011).

Braden Scale

The Braden Scale (Table 46-2) was developed based on risk factors in a nursing home population (Bergstrom et al., 1987). The Braden Scale comprises six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction and shear. The total score ranges from 6 to 23, and a lower total score indicates a higher risk of pressure ulcer development (Braden & Bergstrom, 1989). The cutoff score for onset of pressure ulcer risk with the Braden Scale in the general adult population is 18 (Ayello & Braden, 2002). The Braden Scale is highly reliable when you use it to identify patients at greatest risk of pressure ulcers (Braden & Bergstrom, 1994; Bergstrom et al., 1987; Keast et al., 2006).

Case Example. Your patient is Mrs. Hetje Lamont, an 85-year-old widow with a recent left-sided stroke who lives alone and who has been admitted to your acute care medical floor. She has obvious slurred speech and some facial drooping; her left arm is flaccid and she tells you she “can't feel it at all.” She has been incontinent of urine since the stroke and is wearing an adult continence product. She seems alert (oriented

► **TABLE 46-2** Braden Scale for Predicting Pressure Sore Risk

Patient's Name _____		Evaluator's Name _____		Date of Assessment _____	
Characteristic	Score: 1	Score: 2	Score: 3	Score: 4	
Sensory Perception					
Ability to respond meaningfully to pressure-related discomfort	1. Completely limited Unresponsive (does not moan, flinch, or gasp) to painful stimuli due to diminished level of consciousness or sedation. OR Limited ability to feel pain over most of body surface.	2. Very limited Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness. OR Has a sensory impairment that limits the ability to feel pain or discomfort over half of body.	3. Slightly limited Responds to verbal commands but cannot always communicate discomfort or need to be turned. OR Has some sensory impairment that limits ability to feel pain or discomfort in 1 or 2 extremities.	4. No impairment Responds to verbal commands. Has no sensory deficit that would limit ability to feel or voice pain or discomfort.	
Moisture					
Degree to which skin is exposed to moisture	1. Constantly moist Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	2. Moist Skin is often, but not always, moist. Linen must be changed at least once a shift.	3. Occasionally moist Skin is occasionally moist, requiring an extra linen change approximately once a day.	4. Rarely moist Skin is usually dry. Linen only requires changing at routine intervals.	
Activity					
Degree of physical activity	1. Bedfast Confined to bed.	2. Chairfast Ability to walk severely limited or nonexistent. Cannot bear own weight or must be assisted into chair or wheelchair.	3. Walks occasionally Walks occasionally during day but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	4. Walks frequently Walks outside the room at least twice a day and inside room at least once every two hours during waking hours.	
Mobility					
Ability to change and control body position	1. Completely immobile Does not make even slight changes in body or extremity position without assistance.	2. Very limited Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.	3. Slightly limited Makes frequent though slight changes in body or extremity position independently.	4. No limitations Makes major and frequent changes in position without assistance.	
Nutrition					
Usual food intake pattern	1. Very poor Never eats a complete meal. Rarely eats more than one-third of any food offered. Eats two servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement. OR Is NPO or maintained on clear liquids or IVs for more than five days.	2. Probably inadequate Rarely eats a complete meal and generally eats only about half of any food offered. Protein intake includes only three servings of meat or dairy products per day. Occasionally will take a dietary supplement. OR Receives less than optimum amount of liquid diet or tube feeding.	3. Adequate Eats over half of most meals. Eats a total of four servings of protein (meat, dairy products) each day. Occasionally will refuse a meal but will usually take a supplement if offered. OR Is on a tube feeding or total parenteral nutrition regimen that probably meets most nutritional needs.	4. Excellent Eats most of every meal. Never refuses a meal. Usually eats a total of four or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.	

► TABLE 46-2 Braden Scale for Predicting Pressure Sore Risk—cont'd

Characteristic	Score: 1	Score: 2	Score: 3	Score: 4
Friction and Shear				
	1. Problem Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction.	2. Potential problem Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	3. No apparent problem Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair at all times.	
				TOTAL SCORE

NPO, Nothing by mouth.

to time, place, person) but has been noted to be “a bit confused and weepy at times.” Her status has been nothing by mouth (NPO) for the past 48 hours, in preparation for a swallowing assessment. (She is currently receiving only IV normal saline.) Her daughter tells you that Mrs. Lamont “has been eating like a bird” for the past few weeks.

When you come to the bedside, she is lying on her right side and has difficulty moving without help. She is too weak to ambulate and needs assistance to sit in a chair.

Questions:

- What is her score on the Braden Risk Assessment Tool?
- From the subscore results, what interventions would be appropriate?
- How often would you reassess your patient for risk of skin breakdown?

Classification of Pressure Ulcers

You need to assess pressure ulcers at regular intervals using systematic variables to evaluate wound healing, plan appropriate interventions, and evaluate progress. One method you can use for assessment of a pressure ulcer is a staging system. Staging systems for pressure ulcers are based on your description of the depth of tissue destroyed. Accurate staging requires knowledge of the skin layers. A major drawback of a staging system is that you cannot stage an ulcer covered with necrotic tissue because the necrotic tissue is covering the depth of the ulcer (Figure 46-9). The necrotic tissue must be debrided or removed to expose the wound base to allow for assessment.

The National Pressure Ulcer Advisory Panel (NPUAP) (2007a) has proposed a four-stage classification system with an additional deep tissue injury (DTI) descriptor (Table 46-3). Pressure ulcer staging describes the pressure ulcer depth at the point of assessment. Thus, once you have staged the pressure ulcer, this stage endures even as the pressure ulcer heals. Pressure ulcers do not progress from a stage III to a stage I; rather a stage III ulcer demonstrating signs of healing is described as a healing stage III pressure ulcer (Nix, 2007). In 2007, the NPUAP redefined the definition of a pressure ulcer and the

Figure 46-9 Pressure ulcer with tissue necrosis.

stages of pressure ulcers, including the original four stages, by adding two stages on deep tissue injury and unstageable pressure ulcers (Box 46-6).

In addition, Bennett (1995) suggested that when you assess patients with darkly pigmented skin, proper lighting is important to accurately assess the skin (see Box 46-2). Either natural light or a halogen light is recommended. This prevents the blue tones that fluorescent light sources produce on darkly pigmented skin, which interfere with accurate assessment.

For a wound with **nonviable tissue**, you will need to include the amount (percentage) and appearance (colour) of viable and nonviable tissue. This will assist you in developing the appropriate plan of care based on the healing ability of the wound.

Granulation tissue is red, moist tissue composed of new blood vessels, the presence of which indicates progression toward healing. Soft yellow or white tissue is characteristic of **slough** (a stringy substance attached to the wound bed), and you will need to remove this before the wound is able to heal. Black or brown necrotic tissue is **eschar**, which will also need to be removed before healing can proceed. Remember, sharp debridement of a wound, to remove nonviable tissue, can be performed only by a nurse who has the appropriate

knowledge, skill, and clinical judgement and agency or institution policy and procedure in place.

The measurement of the size of the wound provides overall changes in size, which is an indicator for wound healing progress (Nix, 2007). Consistent measurement of length times width using a disposable ruler is the best way to ensure appropriate documentation of the progress of wound healing over

time (Langemo et al., 2008). Obtain depth by using a sterile cotton-tipped applicator to gently probe for tunnelling and undermining in the wound bed.

Wound **exudate** describes the amount, colour, consistency, and odour of wound drainage and is part of the wound assessment. Excessive exudate usually indicates presence of an infection. You should also evaluate the condition of the skin

► **TABLE 46-3** Guidelines for Staging Pressure Ulcers

The following criteria can be used as a visual aid to help identify and appropriately stage pressure ulcers. The definitions were derived from work done by the National Pressure Ulcer Advisory Panel and published in February 2007.

Suspected Deep Tissue Injury

Purple or maroon localized area of discoloured intact skin or blood-filled blister due to damage of underlying soft tissue from pressure or shear or both. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared to adjacent tissue.

Stage I

Intact skin with nonblanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its colour may differ from the surrounding area.

Stage II

Partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or an open or ruptured serum-filled blister.

Stage III

Full thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunnelling.

Continued

► **TABLE 46-3** Guidelines for Staging Pressure Ulcers—cont'd

Stage IV

Full thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often includes undermining and tunnelling.

Unstageable

Full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, grey, green, or brown) or eschar (tan, brown, or black), or both, in the wound bed.

► **BOX 46-6** National Pressure Ulcer Advisory Panel Staging Guidelines

Suspected Deep Tissue Injury

Please refer to Table 46-3 for a description of a suspected deep tissue injury.

Further Description

Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue, even with optimal treatment.

Stage I

Please refer to Table 46-3 for a description of a stage I pressure ulcer.

Further Description

The area may be painful, firm, soft, warmer, or cooler as compared with adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones. The stage may indicate “at-risk” persons (a heralding sign of risk).

Stage II

Please refer to Table 46-3 for a description of a stage II pressure ulcer.

Further Description

The stage presents as a shiny or dry shallow ulcer without slough or bruising.* This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.

Stage III

Please refer to Table 46-3 for a description of a stage III pressure ulcer.

Further Description

The depth of a stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep stage III pressure ulcers. The bone or tendon is not visible or directly palpable.

Stage IV

Please see Table 46-3 for a description of a stage IV pressure ulcer.

Further Description

The depth of a stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and these ulcers can be shallow. Stage IV ulcers can extend into muscle or supporting structures (e.g., fascia, tendon, or joint capsule), or both, making osteomyelitis possible. Exposed bone or tendon is visible or directly palpable.

Unstageable

Please refer to Table 46-3 for a description of an unstageable pressure ulcer.

Further Description

Until enough slough or eschar is removed to expose the base of the wound, the true depth, and, therefore, stage cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as “the body’s natural (biological) cover” and should not be removed. The staging system was defined by Shea in 1975 and provides a name to the amount of anatomical tissue loss. The original definitions were confusing to many clinicians and led to inaccurate staging of ulcers associated with or due to perineal dermatitis and those due to deep tissue injury.

*Bruising indicates suspected deep tissue injury.

Source: National Pressure Ulcer Advisory Panel. (2007). *Pressure ulcer definitions*. Retrieved from http://www.npuap.org/documents/NPUAP2007_PU_Def_and_Descriptions.pdf.

surrounding the wound for redness, warmth, maceration, or edema (swelling). The presence of any of these factors on the periwound skin indicates wound deterioration.

Wound Classifications

A **wound** is a disruption of the integrity and function of tissues in the body (Baharestani, 1994). It is imperative that you understand that *all wounds are not created equal*. Understanding the etiology of a wound is important because the treatment for the wound varies, depending on the underlying disease process. Some treatments are even harmful to certain wounds, so you always need to obtain a complete history, including the etiology of the wound.

You can classify wounds in many ways. Wound classification systems describe the status of skin integrity, cause of the wound, severity or extent of tissue injury or damage, cleanliness of the wound (Table 46-4), or descriptive qualities of wound tissue such as colour (Figure 46-10). Wound classifications enable you to understand the risks associated with a wound and implications for healing.

Process of Wound Healing

Wound healing involves integrated physiological processes. The tissue layers involved and their capacity for regeneration determine the mechanism for repair of any wound (Doughty & Sparks-Defriese, 2007). Two types of wounds are those with loss of tissue and those without. A clean surgical incision is an example of a wound with little tissue loss. The surgical wound heals by **primary intention**. The skin edges are **approximated**, or closed, and the risk of infection is low.

Healing occurs quickly, with minimal scar formation, as long as infection and secondary breakdown are prevented (Doughty & Sparks-Defriese, 2007). In contrast, a wound involving loss of tissue, such as a burn, pressure ulcer, or severe laceration, heals by **secondary intention**. The wound is left open until it becomes filled by scar tissue. It takes longer for a wound to heal by secondary intention; thus, the chance of infection is greater. If scarring from secondary intention is severe, loss of tissue function is often permanent (Figure 46-11).

Wound Repair

Partial-thickness wounds are shallow wounds involving loss of the epidermis (top layer) and possibly partial loss of the dermis. Epidermal wounds, such as a clean surgical wound or an abrasion, heal by regeneration. However, full-thickness wounds extending into the dermis (involving both layers of tissue) heal by scar formation because deeper structures do not regenerate. Pressure ulcers are an example of full-thickness wounds.

Partial-Thickness Wound Repair. Three components make up the healing process of a partial-thickness wound: inflammatory response, epithelial proliferation (reproduction) and migration, and re-establishment of the epidermal layers. Tissue trauma causes the *inflammatory response*, which, in turn, causes redness and swelling to the area, as well as a moderate amount of serous exudate. Normally, this response is limited to the first 24 hours after wounding. Epithelial cells begin to regenerate, providing new replacement cells. This *epithelial proliferation and migration* starts at the wound edges and the epidermal cells lining the epidermal appendages, allowing for quick resurfacing. Epithelial cells begin migrating across the wound bed soon after wounding. *A wound left open to air can resurface within six to seven days, whereas a wound that is kept*

► TABLE 46-4 Wound Classification

Description	Causes	Implications for Healing
Onset and Duration		
Acute		
A wound that proceeds through an orderly and timely reparative process that results in sustained restoration of anatomical and functional integrity.	Trauma, a surgical incision.	Wounds are usually easily cleaned and repaired. Wound edges are clean and intact.
Chronic		
Wound that fails to proceed through an orderly and timely process to produce anatomical and functional integrity.	Vascular compromise, chronic inflammation, or repetitive insults to the tissue (Doughty & Sparks-Defriese, 2007).	Continued exposure to insult impedes wound healing.
Healing Process		
Primary Intention		
Wound that is closed.	Surgical incision, wound that is sutured or stapled.	Healing occurs by epithelialization; heals quickly with minimal scar formation.
Secondary Intention		
Wound edges are not approximated.	Pressure ulcers, surgical wounds that have tissue loss.	Wound heals by granulation tissue formation, wound contraction, and epithelialization.
Tertiary Intention		
Wound is left open for several days, then wound edges are approximated.	Wounds that are contaminated and require observation for signs of inflammation.	Closure of wound is delayed until risk of infection is resolved (Doughty & Sparks-Defriese, 2007).

moist can resurface in four days. The difference in the healing rate is related to the fact that epidermal cells only migrate across a moist surface. In a dry wound, the cells migrate down into a moist level before migration can occur (Doughty & Sparks-Defriese, 2007). New epithelium is only a few cells thick and must undergo re-establishment of the epidermal layers. The cells slowly re-establish normal thickness and appear as dry pink tissue.

Full-Thickness Wound Repair. Inflammatory, proliferative, and remodelling phases are involved in the healing process of a full-thickness wound. Note the differences between partial and full-thickness wounds.

Figure 46-10 Wounds classified by colour assessment. **A**, Black wound. **B**, Yellow wound. **C**, Red wound. **D**, Mixed-colour wound. **Source:** Courtesy Scott Health Care—A Molnlycke Company, Philadelphia, PA.

Figure 46-11 **A**, Wound healing by primary intention such as a surgical incision. Wound healing edges are pulled together and approximated with sutures or staples, and healing occurs by connective tissue deposition. **B**, Wound healing by secondary intention. Wound edges are not approximated, and healing occurs by granulation tissue formation and contraction of the wound edges. **Source:** Bryant, R. A., & Nix, D. P. (Eds.). (2007). *Acute and chronic wounds: Nursing management* (3rd ed.). St Louis, MO: Mosby. Used with permission.

Inflammatory Phase. The inflammation stage is the body's reaction to wounding, beginning within minutes of injury and, in full thickness wounds, lasts approximately three days. During **hemostasis**, injured blood vessels constrict, and platelets gather to stop bleeding. Clots form a **fibrin** matrix that later provides a framework for cellular repair. Damaged

tissue and mast cells secrete histamine, resulting in vasodilation of surrounding capillaries and exudation of serum and white blood cells into damaged tissues. This results in localized redness, edema, warmth, and throbbing. The inflammatory response is beneficial, and attempting to cool the area or reduce the swelling has no value unless the swelling occurs within a closed compartment (e.g., ankle or neck).

Leukocytes (white blood cells) reach the wound within a few hours. The primary white blood cell is the neutrophil, which begins to ingest bacteria and small debris. The second important leukocyte is the monocyte, which transforms into macrophages.

The macrophages are the "garbage cells" that clean a wound of bacteria, dead cells, and debris by phagocytosis. Macrophages continue the process of clearing the wound of debris and release growth factors that attract fibroblasts, the cells that synthesize collagen (connective tissue). Collagen appears as early as the second day and is the main component of scar tissue.

In a clean wound, the inflammatory phase accomplishes control of bleeding and establishes a clean wound bed. The inflammatory phase is prolonged if too little inflammation occurs, as in debilitating diseases such as cancer or after the administration of steroids. Too much inflammation also decreases the speed of healing as arriving cells compete for available nutrients.

Proliferative Phase. The proliferative phase, in which new blood vessels appear as reconstruction progresses, begins, lasting from 3 to 24 days. The main activities during this phase are filling of the wound with granulation tissue, contraction of the wound, and resurfacing of the wound by epithelialization. Fibroblasts, which synthesize collagen, are present in this phase, providing the matrix for granulation, in turn supporting re-epithelialization. Collagen provides strength and structural integrity to a wound. During this period, the wound contracts to reduce the area that requires healing (**wound contraction**). Lastly, epithelial cells migrate from the wound edges

to resurface. In a clean wound, when the proliferative phase is complete, the vascular bed has been re-established and the area filled with replacement tissue (collagen/granulation tissue), and the surface has been repaired (**epithelialization**). Impairment of healing during this stage usually results from systemic factors such as age, anemia, hypoproteinemia, and zinc deficiency.

Remodelling. Maturation, the final stage of healing, can take up to two years to occur, depending on the depth and extent of the wound. The collagen scar continues to reorganize and gain strength for several months. Usually, scar tissue contains fewer pigmented cells (melanocytes) and has a lighter colour than normal skin. However, you need to pay attention since a healed wound usually does not have the tensile strength of the tissue it replaces.

All chronic wounds described in this chapter are discussed in detail in the RNAO Best Practice Guidelines, which are readily available to you online at <http://www.rnao.org>.

Skin Tears

Aging skin is at a greater risk of developing skin tears because of the thinning of the epidermis. Dehydration, poor nutrition, prolonged use of corticosteroids, impaired sensory perception, and cognitive impairment are all risk factors for skin breakdown. When moving older adult patients in bed or transferring them from bed to gurney for tests, for example, you need to be careful in your handling of the patients. Skin tears and bruising are common problems in this population (Figure 46-12). Any open area on the skin creates the potential for

Figure 46-12 Skin tear. **Source:** Courtesy of Rose Hamm. Cain, J. E. (2009). *Mosby's PDQ for wound care* (p. 18). St Louis, MO: Mosby.

infection (portal of entry for bacteria). Using tape or adhesive dressings on fragile skin can also precipitate skin tears. The use of simple Telfa pads held in place with a woven cotton wrapped bandage (e.g., Kling wrap) or a soft silicone dressing that will not adhere to the skin is effective in protecting the area from further damage and supporting wound healing.

Venous and Arterial Wounds

Venous and arterial wounds are the result of poor circulation and occur in the lower extremities. Venous ulcers are the most common type of lower extremity wound and account for approximately 80% of leg wounds. In addition, these wounds have a recurrence rate of 70% (RNAO, 2007).

Venous Ulcers. Venous ulcers are superficial and irregular in shape (Figure 46-13, A). These wounds usually have a large amount of exudate caused by edema in the surrounding tissue. Venous insufficiency is related to weak vein walls in the legs; furthermore, limited range of motion in the ankle decreases the ability of the calf muscle to pump. Serum and red blood cells leak into the surrounding tissue, which causes the characteristic brownish hemosiderin staining of tissue and skin. In chronic venous insufficiency, the edema in the tissue becomes firm and the lower legs develop a wooden-like appearance, called lipodermatosclerosis.

Treatment of Venous Leg Ulcers. It is important that you assess the ankle-brachial pressure index before using compression therapy to prevent, treat, or diminish edema in the lower legs (Vowden & Vowden, 2001). Because venous leg ulcers are often hard-to-heal wounds, patients may have tried a variety of products, such as lanolin in topical moisturizers, topical antibiotics, or others. These products may create allergic contact dermatitis, and it is best to avoid anything but the most simple, natural products to clean, debride, moisten, and cover. Use normal saline, autolytic debriding agents, preservative-free hydrogels, and soft silicone dressings. Avoid products with preservatives, chemicals in the dressing, and fragrances. Edema control is essential, but many patients are not willing to try or maintain compression therapy. A wound care specialist with training in compression therapy is helpful in assisting you to determine (1) whether the patient has adequate blood flow to allow for compression and (2) different types of compression treatments that may be better suited to certain patients and their goals, especially as lifestyle modifications are usually required to heal venous ulcers.

Arterial Ulcers. Arterial ulcers (also called ischemic ulcers) are caused by inadequate blood flow to the lower extremity (unlike venous ulcers, which are caused by poor

Figure 46-13 A, Venous leg ulcer. B, Arterial lower limb wound. **Source:** Bryant, R., & Nix, D. (2007). *Acute and chronic wounds: Current management concepts* (3rd ed., Plates 34 and 35). St Louis, MO: Mosby.

blood return). Arterial ulcers have a “punched-out” appearance that is both deeper and smaller than venous ulcers. They are often located on the feet, over the tips of the toes, or on the toe joints, but are also found on other locations on the lower leg (Figure 46-13, B). Arterial wounds may be necrotic (black, crusted) in appearance or have very pale wound beds. The legs of a patient with arterial disease are thin and have shiny, taut, and hairless skin with an almost translucent appearance.

Because of the nature of this disease, arterial wounds are quite resistant to healing and could be considered as “maintenance” wounds, where the goal is to provide comfort and protection from infection. These wounds are not good candidates for debridement because poor blood flow will limit ability to heal. The best option for treatment is to keep these wounds clean and dry. Often, you can make a solution of povidone (Betadine) (10% in a 1% solution) using 0.25 povidone to 0.75 normal saline. When you soak the gauze pads in the solution, place them in or on the wound, and change once daily; this will decrease bacteria in the wound and promote drying of the tissue. Both of these results are useful in nonhealing wounds such as arterial ulcers.

Diabetic Ulcers

In Canada, more than 9 million people are living with diabetes or prediabetes (where blood sugar is higher than normal range), according to the Canadian Diabetes Association (2008). The Aboriginal population has much higher percentages of individuals with diabetes (25% of Aboriginal individuals older than 65 years have diabetes). Diabetes is a disease that requires major lifestyle changes, including careful monitoring of blood glucose. Complications related to poorly controlled diabetes have serious results: renal failure, which may require dialysis; diabetic neuropathy, which may lead to limb amputation (Figure 46-14); and retinal neuropathy, which leads to blindness. People with diabetes have compromised healing potential. Any break in the skin can cause long-term problems because these wounds resist healing. Forty-five percent of lower extremity amputations occur in individuals with diabetes. One lower limb amputation of a nontraumatic nature (e.g., diabetes-related) will result in a second limb amputation within three years and death within five years (Tentolouris et al., 2004). These are sobering statistics and reinforce how important it is for you to provide education as well as careful

assessment and early intervention to your patients with diabetes.

Diabetic ulcers occur because of neuropathic changes related to diabetes. They most commonly are found over bony prominences located on the plantar surface of the foot, over the metatarsal heads, and beneath the heels. These changes include sensory neuropathy, loss of protective sensation (e.g., a decrease in the ability to feel pain or temperature change); autonomic neuropathy, or absence of sweating leading to dry skin with fissures, cracks, and calluses over pressure points (heels and ball of the foot); and motor neuropathy, resulting in changes in muscle contractions leading to high arches and cocked-up “hammer” toes. These contribute to pressure points, creating calluses (Figure 46-15).

Assessment. Assessment of the feet in patients with diabetes with a monofilament test (CAWC, 2006) determines the extent of neuropathy (Figure 46-16). However, in patients with diabetes, you can assume that peripheral neuropathy is a risk, and you should conduct education and close inspection and palpation of the feet and lower legs. Prevention starts with instructing patients on appropriate footwear, including wearing hard-soled shoes at home, testing water temperature before bathing or showering, and good foot care, from a certified foot-care specialist such as a chiropodist.

Figure 46-14 Person with above-knee amputation.

Figure 46-16 Monofilament test.

Diabetic Wound Treatment. If the diabetic wound can heal, then necrotic tissue and callus buildup must be debrided to establish a clean wound bed and diminish pressure. Sharp or surgical debridement should be performed only by a qualified health care provider (RN or MD) with appropriate skills and knowledge and supported by agency or institution policy regarding sharp and surgical debridement. Incorrect sharp or surgical debridement can significantly harm your patient. Diabetic wounds may be prophylactically treated with some form of topical antimicrobial dressing. If the patient complains of pain at the wound site, particularly persistent pain, you should suspect osteomyelitis (bone infection). Ensure that the physician or advanced practice nurse primarily responsible for the patient is aware of this so appropriate action can be taken.

Malignant or Fungating Wounds

Cancer tumours may extrude through the skin as swollen masses with numerous fissures that drain purulent, often very malodorous exudate, that sometimes bleed when cleansed or touched. Typical sites for fungating wounds are the side of the face or neck and the breast or groin area (Figure 46-17). These wounds are not only painful at dressing change but also often embarrass the patient because of their odour and unsightliness. They are malignant wounds that will not heal, but the tumours may be reduced in size with radiation or chemotherapy.

Care of the malignant or fungating wound requires attention to environmental and extrinsic issues such as odour, drainage, and appearance of the wound. Odour control may be difficult and may require topical antifungal or antimicrobial dressings such as metronidazole (Flagyl) or a topical silver dressing. Various types of charcoal dressings are also available to provide odour management but are not always effective once they are wet. To avoid trauma to the wound bed, do not use adhesive dressings but use atraumatic dressings such as soft silicone, which will allow for moisture vapour transfer and will decrease pain at dressing changes. Barrier films and the use of silicone (dimethicone)-based creams will provide supportive care and protect the periwound skin. Minimizing the frequency of dressing changes as well as using "low-profile," nonbulky dressings will enhance quality of life.

Acute and Surgical Wounds

You may be in situations in which you are assessing a wound, either at the time of injury before treatment, or after therapy, when the wound is relatively stable. Each situation requires you to make different observations and to take different actions. Regardless of the setting, it is important that you obtain information regarding the cause and history of the wound (see Box 46-4).

Emergency Setting, or Acute, Wounds. You will see wounds in any setting, including clinic, emergency department, youth camps, or your own backyard. When you judge a patient's condition to be stable because of the presence of spontaneous breathing, a clear airway, and a strong carotid pulse (see Chapter 38), inspect the wound for bleeding. The type of wound determines criteria for inspection. For example, a patient presenting with an abrasion would not likely require you to inspect for signs of internal bleeding, but you should do so in the event of a puncture wound.

An **abrasion** is superficial with little bleeding and is considered a partial-thickness wound. The wound often appears "weepy" because of plasma leakage from damaged capillaries. A **laceration**, which is a jagged, unintentional (i.e., nonsurgical) wound, sometimes bleeds more profusely, depending on the wound's depth and location. For example, minor scalp lacerations tend to bleed profusely because of the rich blood supply to the scalp. Lacerations greater than 5 cm long or 2.5 cm deep cause serious bleeding. Puncture wounds bleed in relation to the depth and size of the wound; for example, a nail puncture does not cause as much bleeding as a knife wound. The primary dangers of puncture wounds are internal bleeding and infection.

Inspect the wound for contaminate material. Most traumatic wounds are dirty. Soil, broken glass, shreds of cloth, and foreign substances clinging to penetrating objects sometimes become embedded in the wound.

Your next step is to assess the size (including depth) of the wound. A deep laceration requires suturing. A large open wound may expose bone or tissue that needs to be protected.

When the injury is a result of trauma from a dirty penetrating object, determine when the patient last received a tetanus toxoid injection. Tetanus bacteria reside in soil and in the gut of humans and animals. A tetanus antitoxin injection is necessary if the patient's last one was more than five years ago.

Stable Setting, or Surgical Wounds. When the patient's condition is stabilized (e.g., after surgery or treatment), assess the wound to determine its healing progress. If the wound is covered by a dressing and the dressing is intact and not saturated with drainage, do not directly inspect the wound unless you suspect serious complications. Here, you only need to inspect the dressing and external drains.

Change dressings contaminated with external drainage (e.g., feces or urine) and saturated dressings with leakage to periwound tissue. When doing so, take care to avoid accidental removal or displacement of underlying drains. Because removal of dressings may be painful, assess the patient's need for an analgesic, and once ordered, make sure it is given at least 30 minutes before exposing the wound.

Wound Appearance. Are wound edges closed? A surgical incision healing by primary intention should have clean, well-approximated edges. A **puncture** wound is usually a small, circular wound with the edges coming together toward the centre. Crusts from exudate often form along wound edges.

▶ TABLE 46-5

Assessment of Abnormal Healing in Primary and Secondary Intention Wounds

Primary Intention	Secondary Intention Wounds
Wounds' incision line poorly approximated	Pale or fragile granulation tissue; granulation tissue bed is excessively dry or moist
Drainage present more than three days after closure	Exudate present
Inflammation decreased in first three to five days after injury	Necrotic or sloughy tissue present in wound base
No epithelialization of wound edges by day 4	Epithelialization not continuous
No healing ridge by day 9	Fruity, earthy, or putrid odour present
	Presence of fistula(s), tunnelling, undermining

Adapted from Stotts, N. A., & Cavanaugh, C. E. (1999). Assessing the patient with a wound. *Home Healthcare Nurse*, 17(1), 27.

If the wound edges are separated, you need to inspect the condition of tissue at the wound base. Look for complications such as dehiscence and evisceration. The outer edges of a wound normally appear inflamed for the first 2 to 3 days, but this slowly disappears. Within 7 to 10 days, a normally healing wound resurfaces with epithelial cells, and edges close.

Table 46-5 lists assessment characteristics for abnormal wound healing in primary and secondary wounds. If an infection develops, the area directly surrounding the wound becomes inflamed and swollen.

Skin discolouration usually results from bruising of interstitial tissues or hematoma formation. Blood collecting beneath the skin first takes on a bluish or purplish appearance. Gradually, as clotted blood is broken down, shades of brown and yellow appear.

Character of Wound Drainage. Note the amount, colour, odour, and consistency of drainage. The amount of drainage depends on the location and extent of the wound. For example, drainage is minimal after a simple appendectomy. In contrast, a large abscess may drain a moderate amount for several days. When you need an accurate measurement of the amount of drainage within a dressing, weigh the dressing and compare it with the weight of the same dressing when clean and dry. The general rule is that 1 g of drainage equals 1 mL of drainage volume. Another method of quantifying wound drainage is to chart the number of dressings used and frequency of changes. An increase or decrease in number or frequency of dressings will indicate a relative increase or decrease in wound drainage.

The colour and consistency of drainage vary depending on the type of drainage, including **serous**, **sanguineous**, **serosanguineous**, and **purulent** (see Table 46-6). If drainage has a pungent or strong odour, you should suspect infection.

Describe the wound's appearance according to the characteristics observed. An example of accurate recording follows:

Abdominal incision is 5 cm in width, in RLQ (right lower quadrant); wound edges well approximated without inflammation or exudate.

▶ TABLE 46-6 Types of Wound Drainage

Type	Appearance
Serous	Clear, watery plasma 
Purulent	Thick, yellow, green, tan, or brown 
Serosanguineous	Pale, red, watery: mixture of clear and red fluid 
Sanguineous	Bright red: indicates active bleeding 

1.2 cm diameter circle of serous drainage present on one 4 × 4 gauze changed every 8 hours.

Drains. If a large amount of drainage is anticipated, a drain is often inserted in or near a surgical wound. Some drains are sutured in place. *Exercise caution when changing the dressing around drains, regardless of whether they are sutured, to prevent accidental removal.* A Penrose drain lies under a dressing; at the time of placement, a pin or clip is placed through the drain to prevent it from slipping farther into a wound (Figure 46-18). It is usually the nurse's responsibility to pull or advance the drain as drainage decreases to permit healing deep within the wound site.

When you assess the number of drains, drain placement, character of drainage, and condition of collecting equipment, first observe the security of the drain and its location with respect to the wound. Next, note the character of drainage. If a collecting device is available, measure the drainage volume. Because a drainage system needs to be patent, look for drainage flow through the tubing, as well as around the tubing.

A sudden decrease in drainage through the tubing may indicate a blocked drain, which may require surgical revision. Contact the physician in this case. When a drain is connected to suction, assess the system to be sure that the pressure ordered is being exerted. Evacuator units such as a Hemovac or Jackson-Pratt (Figure 46-19) exert a constant low pressure as long as the suction device (bladder or bag) is fully compressed.

These types of drainage devices are often referred to as self-suction. If the evacuator device is unable to maintain a vacuum on its own, notify the surgeon, who will then order a secondary vacuum system (such as wall suction). If fluid accumulates within the tissues, wound healing will not progress at an optimal rate, increasing risk of infection.

Wound Closures. Surgical wounds are closed with staples, sutures, or wound closures. A frequent skin closure is the stainless steel staple. The staple provides more strength than nylon or silk sutures and causes less irritation to tissue. However, you should look for irritation around staple or suture sites and note whether closures are intact. Normally, for the first two to three days after surgery, skin around sutures or staples is edematous. Continued swelling indicates that closures are too tight. Overly tight suture material may cut into the skin, which can lead to wound separation or wound dehiscence. Early suture removal reduces formation of defects along the suture line and minimizes chances of unattractive scar formation.

Tissue adhesive such as Dermabond forms a strong bond across apposed wound edges, which allows normal healing to occur below. It can be used to replace small sutures for

incisional repair. The product is applied across the approximated wound edges, which are then held together until the solution dries, providing an adhesive closure. Although surgeons generally use it for small superficial lacerations, some may use it on larger wounds, where subcutaneous sutures are needed (Bruns & Worthington, 2000).

Palpation of the Wound. When inspecting a wound, observe swelling or separation of wound edges. Wearing sterile gloves, lightly press the wound edges to detect localized areas of tenderness or drainage collection. If pressure causes fluid to be expressed, note the character of the drainage. The patient is normally sensitive to palpation of wound edges; however, extreme tenderness may be indicative of infection.

Wound Cultures. If you detect purulent or suspicious-looking drainage, you may need to obtain a specimen of the drainage for culture (see Chapter 32). Never collect a wound culture sample from old drainage. Resident colonies of bacteria from the skin grow within exudate and are not always the true causative organisms of a wound infection. Clean a wound first with normal saline to remove skin flora. Aerobic organisms grow in superficial wounds exposed to the air, and anaerobic organisms tend to grow within body cavities. Use a different method of specimen collection for each type of organism as per agency policy (Box 46-7). Swab a wound from the healthiest looking tissue to obtain results consistent with the infectious condition of the wound. It is also appropriate to swab any areas with undermining. See Figure 46-20 for a description of how to swab a wound.

Gram stains, which result in more appropriate treatment earlier in the course of infection than do cultures, are often also performed, but do not usually require any additional specimens. The gold standard of wound culture is tissue biopsy, obtained by physician or nurse with specialized training (Stotts, 2007b).

Complications of Wound Healing

Hemorrhage. Hemorrhage, or bleeding from a wound site, is normal during and immediately after initial trauma. Hemostasis occurs within several minutes unless large blood vessels are involved or the patient has poor clotting function. Hemorrhages that occur after hemostasis indicate a slipped surgical suture, a dislodged clot, infection, or erosion of a

Figure 46-18 Penrose drain.

► BOX 46-7

Recommendations for Standardized Techniques for Wound Cultures*

Quantitative Swab Procedure

- Clean the wound surface with a *nonantiseptic* (i.e., sterile water or normal saline) solution.
- Use a sterile swab from a culturette tube.
- Rotate the swab in 1 cm² of clean tissue in the open wound (see Figure 46-20). Apply pressure to the swab to elicit tissue fluid (Stotts, 2007b). Insert the tip of the swab into the appropriate sterile container, and transport to the laboratory.

*Check agency policy to determine whether you need to obtain an order from a health care provider.

blood vessel by a foreign object (e.g., a drain). Hemorrhage occurs externally or internally.

You detect internal bleeding by looking for distention or swelling of the affected body part, a change in the type and amount of drainage from a surgical drain, or signs of hypovolemic shock. A **hematoma** is a localized collection of blood underneath the tissues. It appears as a swelling, a change in colour, sensation, or warmth, or a mass that often takes on a bluish discoloration. A hematoma near a major artery or vein is dangerous because pressure from the expanding hematoma obstructs blood flow.

External hemorrhaging is obvious. You observe the dressings covering the wound for bloody drainage. If bleeding is extensive, the dressing soon becomes saturated, and frequently blood drains from under the dressing and pools beneath the patient. *Observe all wounds closely, particularly surgical wounds, in which the risk of hemorrhage is greatest during the first 24 to 48 hours after surgery or injury.*

Infection. Wound infection is the second most common health care–associated infection (nosocomial) (see Chapter 32).

However, infection may not be revealed through a lab culture due to poor culture technique or administration of antibiotics. In fact, all chronic wounds are considered contaminated with bacteria. What differentiates contaminated wounds from infected wounds is the amount of bacteria present. It is generally agreed that infected wounds have more than 100,000 (10^5) organisms per gram of tissue (Stotts, 2007b). The chances of wound infection are greater when the wound contains necrotic tissue, when contaminants are in or near the wound, and when blood supply and local tissue defences are reduced.

Bacterial infection inhibits wound healing. Some contaminated or traumatic wounds show signs of infection early, within two to three days. A surgical wound infection may not develop until day four or five. The patient has a fever, tenderness and pain at the wound site, and an elevated white blood cell count. The edges of the wound appear inflamed. If drainage is present, it is odorous and purulent, and is a yellow, green, or brown colour, depending on the causative organism.

Dehiscence. When a wound fails to heal properly, the layers of skin and tissue separate. This most commonly occurs before collagen formation (3 to 11 days after injury). **Dehiscence** is the partial or total separation of wound layers. A patient at risk of poor wound healing (e.g., poor nutritional status, infection, or obesity) is at risk of dehiscence. However, obese patients have a higher risk because of the constant strain placed on their wounds and the poor healing qualities of fat tissue (Camden, 2007). Dehiscence involves abdominal surgical wounds and may occur after a sudden strain, such as coughing, vomiting, or sitting up (Figure 46-21). Patients often report feeling as though something has given way. *When an increased amount of serosanguineous drainage from a wound occurs, be alert for the potential for dehiscence.* A strategy to prevent dehiscence is to provide support to the area, using a folded thin blanket or pillow placed over an abdominal wound when the patient is coughing. This splints and supports healing tissue when coughing increases intra-abdominal pressure.

Evisceration. With total separation of wound layers, **evisceration** (protrusion of visceral organs through a wound opening) sometimes occurs. It is an emergent condition that requires surgical repair. *When evisceration occurs, you need to quickly place sterile towels soaked in sterile saline over the extruding tissues to reduce the chance of bacterial invasion and drying of the tissues and contact the physician.* If the organs protrude through the wound, blood supply to the tissues is compromised. Do not allow the patient anything by mouth (NPO), observe for signs and symptoms of shock, and prepare the patient for emergency surgery.

Fistulas. A **fistula** is an abnormal passage between two organs or between an organ and the outside of the body. Most fistulas form as a result of poor wound healing or complication of disease, such as Crohn's disease. Trauma, infection, radiation exposure, and diseases such as cancer will prevent tissue layers from closing properly and will allow the fistula tract to form. Fistulas increase the risk of infection and fluid and electrolyte imbalances from fluid loss. Chronic drainage of fluids through a fistula also predisposes a patient to skin breakdown (Box 46-8).

❖ Nursing Diagnosis

Through assessment, clusters of data reveal whether an actual or a risk of *impaired skin integrity* exists. Assessment data may support more than one diagnostic label. For example, a

Figure 46-21 A, Dehiscent wound before wound V.A.C. therapy. B, Dehiscent wound after wound V.A.C. therapy. **Source:** Courtesy Kinetic Concepts, Inc. San Antonio, TX.

► BOX 46-9

Impaired Skin Integrity Related to a Contaminated Wound

Assessment Activities That Define Characteristics

Inspect surface of skin: presence of wound, break in skin integrity
Yellow, foul-smelling drainage from wound
Edges of wound red and warm, not approximated
Sutures remain in place. Inspect wound for signs of healing
Brown-red drainage five days after surgery
Edges of wound not approximated
Obtain patient's temperature, heart rate, white blood cell count, and serum albumin level
Patient is febrile, heart rate is 125 beats per minute, leukocyte (white blood cell) count is $12,000/\text{mm}^3$, and serum albumin level is less than 3.5 mg/100 mL

postoperative patient has purulent drainage from a surgical wound and reports tenderness around the area of the wound. These data support a nursing diagnosis of *impaired skin integrity related to a contaminated wound* (Box 46-9). After completing an assessment of the patient's wound, you would identify nursing diagnoses that will direct supportive and preventive care. Multiple nursing diagnoses are associated with impaired skin integrity and wounds:

- *Risk of infection*
- *Imbalanced nutrition: less than body requirements*
- *Acute or chronic pain*
- *Impaired physical mobility*
- *Impaired skin integrity*
- *Risk of impaired skin integrity*
- *Ineffective tissue perfusion*
- *Impaired tissue integrity*

Some patients are at risk of poor wound healing because of previously defined factors that impair healing. Thus, even though the patient's wound appears normal, you would identify nursing diagnoses, such as *impaired nutrition* or *ineffective tissue perfusion*, that direct nursing care toward support of wound repair.

The nature of a wound can cause problems unrelated to wound healing. *Alteration in comfort* and *impaired mobility* are problems that have implications for the patient's eventual recovery. For example, a large abdominal incision can cause enough pain to interfere with the patient's ability to turn in bed effectively.

❖ Planning

After identifying nursing diagnoses, you develop a plan of care for the patient who is at risk or who has actual impaired skin integrity. During planning, synthesize information from multiple resources (Figure 46-6). Critical thinking ensures that the patient's plan of care integrates all that you know about the individual, as well as key critical thinking elements. Professional standards of practice are especially important to consider when developing your plan of care. Ask yourself what aspects of care you are able to perform without medical orders, what aspects of care you can delegate to other regulated health care providers, and what are the patient goals.

For many of your patients, the wound is only a part of the story. For example, consider the following scenario:

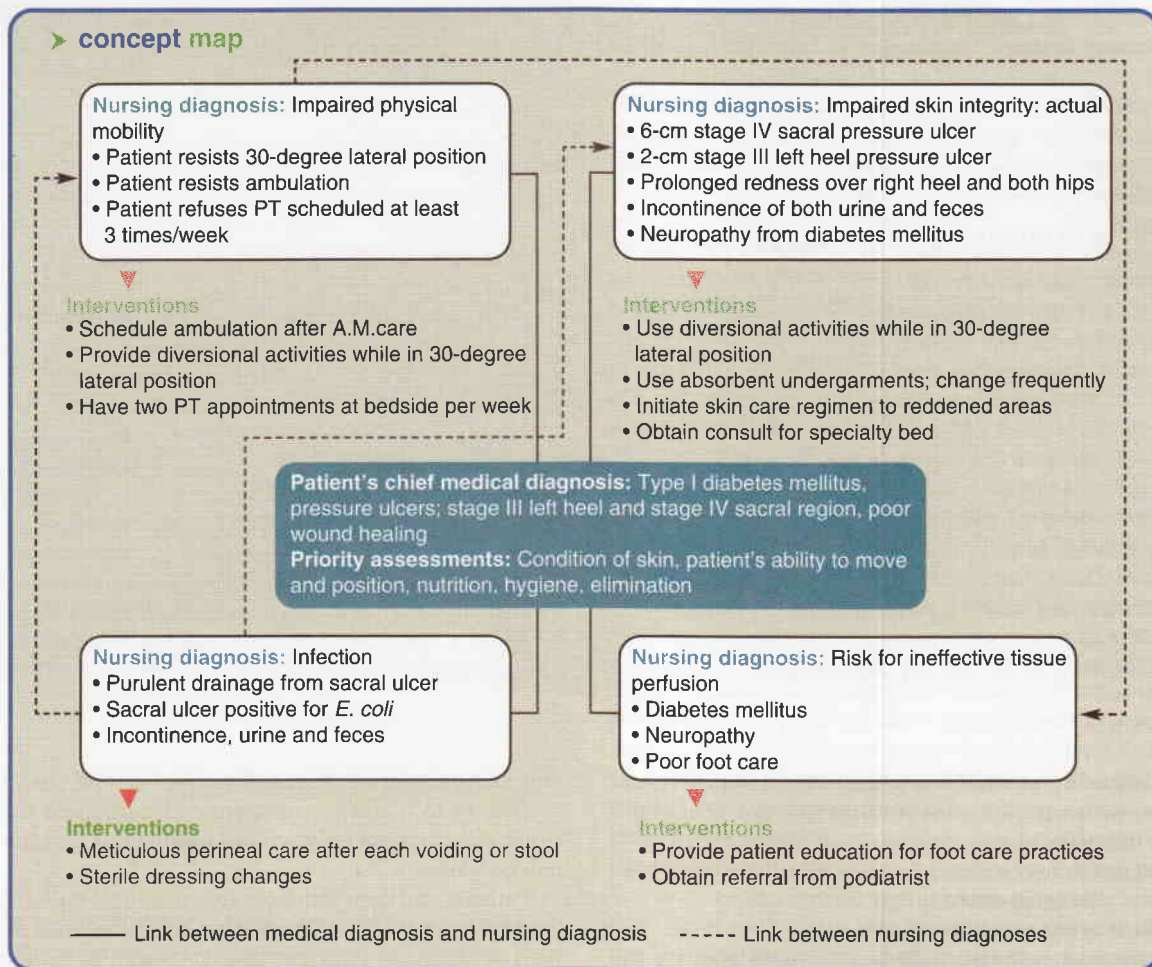

Figure 46-22 Concept map for a patient with a chronic wound.

You are caring for Mrs. Kathy Crane, a 65-year-old woman who lives with her recently retired husband and who has a 30-year history of diabetes mellitus. She currently takes insulin, but her diabetes is poorly controlled because of her inability to adhere to a 1200-calorie diabetic diet and her "hit or miss" approach to testing her serum glucose on a regular basis. She is 32 kg overweight.

For the last 10 years, she has reported decreased sensation in her lower extremities. She does not practise good foot care; she cuts her own toenails and, at home, goes barefoot or wears socks. She regularly soaks her feet in an Epsom-salt footbath because she "read this was good for your feet."

She was admitted to the hospital for elective repair of an abdominal aneurysm. The surgery went well, but postoperatively Mrs. Crane had difficulty ambulating and performing coughing and deep breathing exercises. On her second postoperative day, she developed pneumonia, which required intravenous antibiotics. During the course of her pneumonia, Mrs. Crane stated she was "too tired" to walk or get up to use the commode or toilet. She required an adult continence product as she was now incontinent of urine and stool. She complained of pain when repositioned and would generally reposition herself on her back. Two weeks after her surgery, Mrs. Crane developed a large draining sacral wound, which is now 6 cm in diameter. The base of the wound can be visualized down to bone (stage IV). In addition, she has a smaller, stage III ulcer on her left heel. Skin assessment also reveals areas of prolonged redness over pressure points, especially on the right heel and over both hips.

When planning care for Mrs. Crane, you can use a concept map to individualize care for her, as she has multiple health problems and related nursing diagnoses (Figure 46-22). This map assists you in using critical thinking skills to organize complex patient assessment data and related nursing diagnoses with the patient's chief medical diagnosis. As you identify linkages between nursing diagnoses and medical diagnosis, the concept map also links potential interventions with the patient's health care needs and goals in mind.

Goals and Outcomes

Nursing care is based on the patient's identified needs and priorities. Your first job is to ensure you and the patient are on the same path, regarding the establishment of goals and expected outcomes. In addition, you need to determine whether the wound is likely to heal. For example, a pressure ulcer with unrelieved pressure and/or poor nutritional intake is unlikely to heal. In addition, patients in terminal stages of illness may not have the physiological resources to heal, despite optimal environmental supports. Thus, it is important to plan interventions according to risk of skin breakdown, type and severity of the wound, and complications, such as infection, poor nutrition, and peripheral vascular diseases, which affect wound healing.

► BOX 46-10 Home Care Recommendations for Ulcer or Wound Assessment

Assessment and documentation of the pressure ulcer should occur at least weekly, unless evidence of deterioration exists, in which case you need to reassess both the wound and the patient's overall management immediately. In the home setting, it is essential to include the patient and family in monitoring the progress of the wound.

Psychosocial Assessment and Management

- Assess the patient's resources (e.g., availability and skill of caregivers, finances, equipment). A successful treatment program requires adequate caregiver and equipment resources.
- Evaluate caregivers for their ability to comprehend and implement the treatment requirements.
- Evaluate caregivers for their level of strength and endurance.
- Consider economic factors that may limit the supply and availability of equipment, as well as opportunities to relieve caregivers.
- Use an approach that focuses on the psychosocial and physical factors affecting wound care (Teare & Barrett, 2002).

Ulcer Care Dressings

- Consider caregiver time and ability when selecting a dressing.
- Consider a dressing that, while more expensive per unit, may decrease frequency of dressing change (which is more

cost-effective than a cheaper dressing requiring more frequent dressing change).

Infection Control

- All wounds are colonized; thus, the focus in the home is to avoid introduction of contamination into the wound, either by instruments, dressings, or technique at dressing change (Sibbald et al., 2003).
- Depending on the status of the wound (surgical/acute or chronic), secondary dressings may be clean or sterile, but the contact layer dressing should be from a sterile (unopened) package.
- The "no-touch" technique is generally used. This technique is a method of changing surface dressings without touching the wound or the surface of any dressing that might be in contact with the wound. Adherent dressings should be grasped by the corner and removed slowly, whereas gauze dressings can be pinched in the centre and lifted off (Hart, 2007).
- Place soiled dressings in plastic bag and securely fasten bag closure. Disposal of contaminated dressings in the home should be done in a manner consistent with local regulations and home care agency policies.

A goal frequently identified is to see wound improvement within a two-week period. The outcomes of this goal could include the following:

- Higher percentage of granulation tissue in the wound base
- No further skin breakdown in any body location
- An increase in caloric intake of 10%

These outcomes are reasonable if the overall goal for the patient is to heal the ulcer. Other goals of care for patients with wounds include preventing infection, maintaining skin integrity, comfort, and health promotion.

Setting Priorities

You establish nursing care priorities in wound care based on the comprehensive patient assessment goal expectations and established outcomes. These priorities also depend on whether the patient's condition is stable or acute (emergent). An acute wound needs immediate intervention, whereas in the presence of a chronic, stable wound, other factors, such as mobilization, may have greater priority. No matter what the risk of pressure ulcer development, preventive interventions such as skin care practices, appropriate positioning, and elimination of friction and shear are priorities. Promotion of skin health is also essential. Existing skin breakdown, from skin tears to large chronic wounds, requires ongoing attention because it is frequently the reason for both hospitalization and decrease in quality of life for patients, no matter what the setting. Patient and family preferences, daily activities, and the healing potential of the wound need to be included in the collaborative setting of priorities.

Collaborative Care

Wound care is not just your responsibility, as the nurse caring for this patient. It is a team effort, including physiotherapist, occupational therapist, dietitian, pharmacist, and physician, as well as patient, family, and nurse. With early discharge from health care settings, it is important to consider what resources are required to plan for the patient's ongoing care. Anticipating

wound care needs and related equipment and resources, such as referral to a home care agency or outpatient wound care clinic, supports not only wound healing but also the patient's independence.

Patients and their families often need to continue the objectives of wound management after discharge (Box 46-10). You need to consider caregiver ability, as well as time needed to change a particular dressing when selecting the treatment to use after discharge. In particular, in the community, frequency of home visits is a key factor in resource management. Patients, families, and caregivers need to be provided with education and knowledge so that they understand the importance of good nutrition, pressure off-loading (particularly when sitting in a recliner chair for long periods of time), and how different wound dressings are used. Your role, no matter the health care setting, is to work with the patient and family to develop and support their understanding and involvement to optimize wound healing as much as possible.

❖ Implementation: Preventing Skin Breakdown

Health Promotion

The most effective intervention for problems with skin integrity and wound care is prevention. Prompt, early identification of patient risk factors aids in the prevention of pressure ulcers. Use of a risk assessment tool, such as the Braden Risk Assessment Tool (see Table 46-2) is a first step in identifying a patient's risk of skin breakdown. Table 46-7 provides nursing interventions based on risk factors identified in the Braden Tool. If you identify risk factors, you must follow up with interventions. The three major areas of nursing interventions for prevention of skin breakdown are (1) skin care, including hygiene and moisture management; (2) mechanical loading and support devices, including positioning and use of therapeutic surfaces; and (3) education (RNAO, 2011).

▶ TABLE 46-7

A Quick Guide to Pressure Ulcer Prevention

Risk Factor	Nursing Interventions
Decreased sensory perception	Assess pressure points for signs of nonblanching reactive hyperemia. Provide a pressure-redistribution surface.
Moisture	Assess need for incontinence management. After each incontinent episode, cleanse area with no-rinse perineal cleanser and protect skin with a moisture-barrier ointment.
Friction and shear	Reposition patient by using a drawsheet to lift the patient off the surface. Ensure heels are also supported. Provide a trapeze to facilitate movement. Position patient at a 30-degree lateral turn and limit head elevation to 30 degrees.
Decreased activity or mobility	Establish and post an individualized turning schedule. Ensure functionality of pressure off-loading devices for wheelchair, bed.
Poor nutrition	Assess teeth or dentures; ensure good mouth care. Provide adequate nutritional and fluid intake; assist with intake, as necessary. Consult dietitian for nutritional evaluation.

Topical Skin Care

You need to perform frequent skin assessments (see Box 46-4), at a minimum of once a day; however, high-risk patients may require more frequent skin assessments, such as every shift. In addition, ensure that the patient's skin is clean and dry. Assessment and skin hygiene are two initial defences for preventing skin breakdown. When you clean the skin, avoid soaps and hot water. Use cleansers with nonionic surfactants that are gentle to the skin (CAWC, 2006; RNAO, 2011). Many types of products are available for skin care, and you need to match their use to the specific needs of your patient.

After you cleanse the skin and make sure it is completely dry, apply moisturizer to keep the epidermis well lubricated but not oversaturated. Make an effort to control, contain, or correct incontinence, perspiration, and wound drainage (Bryant & Clark, 2007).

Clinicians find the Agency for Health Care Policy and Research (AHCPR) guidelines on urinary incontinence (1992b) helpful, although the Canadian Urological Association (CUA) (<http://www.cua.org>) has developed Canadian guidelines, accessible on the CUA Web site. Patients who have fecal incontinence and who are also receiving enteral tube feeding provide a management challenge. When patients have an incontinent episode, gently cleanse the area, dry, and apply a thick layer of moisture barrier to the exposed areas. A moisture barrier protects skin from excessive moisture and bacteria found in the urine or stool. Ensure the barrier does not interfere with the function of the adult continence brief. It is helpful to use the expertise of an advanced practice nurse with a focus on wound care or management of incontinence while caring for at-risk patients. Methods for controlling or containing incontinence vary. While medication and surgery are available treatments, you can explore behavioural techniques with your

patient, such as prompted or timed voiding. The RNAO Continence and Constipation Best Practice Guidelines, available at <http://rnao.ca>, provide excellent information to assist you in developing appropriate treatment plans for your patients.

Prior to initiating use of absorbent pads and adult continence briefs, make sure you explore the use of the behavioural techniques mentioned above. Use these absorptive products only as part of the treatment plan for an incontinent patient. Use only products that wick moisture away from the patient's skin (Bryant & Clark, 2007; WOCN, 2010). Use underpads with caution, because some of these pads do not wick the drainage away from the patient's skin and will cause skin damage. In addition, patients who are provided with low air loss or other specialty pressure-relief bed surfaces require continence pads designed specifically for the bed surface.

Positioning

Positioning interventions reduce pressure and shearing force to the skin. Elevating the head of the bed to 30 degrees or less will decrease the chance of pressure ulcer development from shearing forces (RNAO, 2011). Given the importance of repositioning the immobilized patient, according to activity level, perceptual ability, and daily routines (Braden, 2001; RNAO, 2011), a standard turning interval of 1.5 to 2 hours does not always prevent pressure ulcer development in some patients. Regardless, patients need repositioning at least every 2 hours on a schedule. When repositioning, use positioning devices to protect bony prominences (RNAO, 2011). The RNAO guidelines (2011) recommend a 30-degree lateral position, which should prevent positioning directly over a bony prominence. To prevent shear and friction injuries, use a sheet to lift, rather than drag, the patient when changing positions, and ensure the heels are supported as well. Use the expertise of physiotherapists and occupational therapists who are skilled at assessment and treatment modalities for both seating and positioning for beds, chairs, and wheelchairs.

safety alert Incorrect positioning of an immobile patient may create a shearing injury. When repositioning the patient, obtain assistance. With at least one other caregiver, place a drawsheet under the patient, and then grasping the sides of the sheet, use it to lift the patient up and toward the new position. Remember to ensure the heels are not dragging on the bed, as this may contribute to shearing and friction injuries.

If your patient can sit in a chair, limit the duration. For example, if it was determined that the patient should be repositioned every two hours, then the duration of sitting should be less than two hours. Remember, in the sitting position, the pressure on the ischial tuberosities is greater than in the supine position. In addition, encourage patients with some independent mobility to shift weight every 15 minutes when sitting (RNAO, 2011). Shifting weight provides short-term relief on the ischial tuberosities. In addition, have patients sit on a foam, gel, or air cushion to redistribute weight away from the ischial areas, and engage assistance of the physical therapist or occupational therapist to ensure that cushions are correctly inflated and positioned. Rigid and doughnut-shaped cushions are contraindicated because they reduce blood supply to the area, which results in wider areas of ischemia (RNAO, 2011).

After repositioning the patient, reassess the skin. See Box 46-2 for identifying characteristics that indicate early signs of tissue ischemia in darkly pigmented skin. For patients who

have light-toned skin, check for normal reactive hyperemia and blanching.

Never massage the reddened areas. Massaging reddened areas increases breaks in the capillaries in the underlying tissues and increases the risk of injury to those tissues and of pressure ulcer formation (RNAO, 2011).

Support Surfaces (Therapeutic Beds and Mattresses)

A support surface is a specialized device for pressure redistribution designed for management of tissue loads, microclimate, and other therapeutic functions (i.e., mattresses, integrated bed system, mattress replacement, overlay or seat cushion, or seat cushion overlay) (NPUAP, 2007b). A variety of support surfaces exists, including specialty beds and mattresses that reduce the hazards of immobility to the skin and musculoskeletal system. However, none eliminates the need for meticulous nursing care, and no single device eliminates the effects of pressure on the skin.

When selecting support surfaces, thoroughly assess the patient's needs. Knowledge about support surface characteristics (Table 46-8) will assist you in clinical decision making, along with consultations with the physical therapist and occupational therapist.

Fully explain to patients and families why and how these specialty surfaces need to be used (Box 46-11). Some common errors when support surfaces are used are placing the wrong

* BOX 46-11 PATIENT TEACHING

Pressure-Redistribution Surfaces

Objectives

- Patient and family will describe their understanding of the purposes and basic operations of the pressure-redistribution surfaces.

Teaching Strategies

- Explain reasons for the pressure-redistribution surface.
- Explain proper body mechanics while using the pressure-redistribution surface.
- Educate patient and family about the use and care of the pressure-redistribution surface.
- Explain additional pressure-redistribution measures.

Evaluation

- Patient and family will state the basic purposes for the pressure-redistribution surface.
- Patient and family will describe the function of the pressure-redistribution surface.
- Patient and family will demonstrate proper use of the pressure-redistribution surface.

► TABLE 46-8 Support Surfaces

Categories and Definitions	Mechanism of Action	Indications	Examples of Manufacturers' and Product Names
Low-Air-Loss Available in a mattress placed directly on the existing bed frame or an overlay placed directly on top of an existing surface	Pressure redistribution Provides a flow of air to assist in managing the heat and humidity of the skin	Prevention or treatment of skin breakdown	Hill-Rom; Flexair Kinetic Concepts, Inc.; First Step Select; Crown Therapeutics; Select Air Mattress
Nonpowered Any support surface not requiring or using external sources of energy for operation. Examples: foam, interconnected air-filled cells	Pressure redistribution Air moves to and from cells as body position changes	Prevention or treatment of skin breakdown	Crown Therapeutics Roho Dry Floatation Mattress Gaymar Industries/Sof-Care
Air-Fluidized Beds Surfaces that change load distribution properties when powered and when patient is in contact with the surface	Provides pressure redistribution via a fluidlike medium created by forcing air through beads, as characterized by immersion and envelopment	Prevention or treatment of skin breakdown May also be used to protect newly flapped or grafted surgical sites and for patients with excessive moisture	Kinetic Concepts, Inc./ FluidAir/ Hill-Rom/ Clinitron
Lateral Rotation Provides passive motion to promote mobilization of respiratory secretions and provides low-air-loss therapy	Features a support surface that provides rotation about a longitudinal axis, as characterized by degree of patient turn, duration, and frequency	Treatment and prevention of pulmonary complications associated with immobility	Hill-Rom/Total Care Sport/ Kinetic Concepts, Inc./ TriADyne

side of the support surface toward the patient, not plugging in or turning on powered support surfaces, using inappropriate absorbent underlay or bedding, failing to do “hand checks,” and improper inflation (too much or too little) for some support surfaces. Hand checks are done by placing your hand under the support surface (or, if an overlay, between it and the standard mattress or cushion), at the pressure point, with the palm facing up and fingers flat. There should be at least 2.5 cm of support surface between your patient’s pressure point and your hand. If not, the support cushion or bed surface does not provide adequate support.

Education

Education of the patient and caregivers is an important nursing function (Rolstad & Ovington, 2007). What is important is that you individualize your teaching to meet the language, educational level, and learning needs for each patient, especially older patients, or those for whom English is not their first language. You can use a variety of educational tools, including Web-based learning, DVDs and videos, and written materials, when teaching patients and caregivers or family how to prevent and treat pressure ulcers. You can access materials from reputable government, educational, and national organizations such as the Canadian Association of Wound Care (<http://cawc.net>) and the Canadian Association of Enterostomal Therapists (<http://www.caet.ca>). The wound care industry also provides excellent educational materials, although some may be product specific. You can readily access any of these sites through an Internet search engine.

In addition, you need to be aware of the meaning of the experience of a chronic wound for patients and their caregivers (RNAO, 2011). Through research, clinicians are beginning to explore the concerns and issues faced by patients and their frail older spouses caring for their loved ones with pressure ulcers (Goldberg & Beltz, 2010). You need to plan interventions to meet the identified psychosocial needs of patients and their caregivers (CAWC, 2006; RNAO, 2011).

Management of Pressure Ulcers

Treatment of patients with pressure ulcers requires a holistic, team approach (RNAO, 2011). Aspects of pressure ulcer treatment include local care of the wound and supportive measures such as adequate nutrients and redistribution of pressure (Skill 46-2), which may call for the expertise of other members of the interdisciplinary health care team, including physician, physiotherapist, occupational therapist, dietitian, pharmacist, and social worker.

Optimizing wound healing requires monitoring of the wound, but unless infection is suspected or present, the wound will heal best when undisturbed. Many current wound dressings are designed to remain in place for up to a week or even longer, and this approach supports healing in chronic, noninfected wounds (CAWC, 2006; RNAO, 2011). However, this does not diminish the need to regularly assess and document the wound: location, stage, size, tissue type and amount, exudate, and the surrounding skin condition (Nix, 2007).

The use and documentation of a systematic approach to assessment of pressure ulcers leads to better decision making and optimum outcomes (Nix, 2007). Several healing and documentation tools are available for you to use to document wound assessments over time. Using a tool helps link the assessment to outcomes so that an evaluation of the plan of care follows objective criteria (Nix, 2007). For example, the

Pressure Ulcer Status Tool (PSST) (Bates-Jensen, 1995) addresses 15 wound characteristics. You score individual items and total them, providing an overall indication of wound status. The scoring assists in evaluating whether the goals of the wound management plan are effective. Tools such as the PSST may seem overly detailed and time consuming, but when you use them judiciously and regularly, they provide a method of ensuring reliable documentation of nursing actions.

Wound Management. Maintenance of a physiological local wound environment is the goal of effective wound management (Rolstad & Ovington, 2007). To maintain a healthy wound environment, you need to address the following directives: prevent and manage infection, cleanse the wound, remove nonviable tissue, manage exudate, maintain the wound in a moist environment, and protect the wound. A wound will not move through the phases of wound healing if the wound is infected. Prevention of wound infection includes wound irrigation, cleansing, and removal of nonviable tissue.

Cleaning a Wound. Use only noncytotoxic wound cleansers, such as normal saline or commercial wound cleansers, to clean wounds. Noncytotoxic cleansers will not damage or kill fibroblasts and healing tissue (Rolstad & Ovington, 2007). Cytotoxic solutions to absolutely avoid are sodium hypochlorite solution (Dakin’s solution—essentially bleach), acetic acid, povidone-iodine, and hydrogen peroxide. These are *not* to be used in clean granulating wounds because they inhibit wound healing (CAWC, 2006; RNAO, 2011).

Irrigation. Irrigation is a common method of delivering the wound cleansing solution to the wound. Studies have shown that an optimal effective range of irrigation pressures exists that ensure adequate removal of bacteria (RNAO, 2011; Rodeheaver, 2001). To ensure an irrigation pressure within the correct range, use a 35 mL syringe with a 19-gauge angiocatheter or a single 100 mL saline squeeze bottle. Both methods will enhance wound cleansing, but by delivering saline at a pressure between 4 and 15 psi (RNAO, 2011), you will avoid trauma to the wound bed.

Debridement. Debridement is the removal of nonviable, necrotic tissue and is necessary to rid the ulcer of a source of infection, to enable visualization of the wound bed, and to provide a clean base for healing. However, a dry necrotic heel ulcer is an exception. According to the RNAO guidelines (2011), stable, dry, black eschar on heels should not be debrided if no evidence of infection (e.g., pain, purulence, or erythema) appears. The method of debridement—mechanical, autolytic, chemical, or sharp or surgical—will depend on which is most appropriate to the patient’s condition and care goals (RNAO, 2011). During the debridement process, remember that increases in wound exudate, odour, and size are likely to be observed. You will need to assess and effectively manage pain that may occur with debridement (CAWC, 2006; RNAO, 2011).

Mechanical debridement, or a “wet-to-dry” saline gauze dressing, is *not* considered appropriate, as it is nonselective in its removal of both devitalized and viable tissue (CAWC, 2006; RNAO 2011). Biological debridement is the use of maggot therapy. Sterile maggots are used in a wound because they ingest the dead tissue and do not impede granulation (Thomas et al., 2001). Chemical or enzymatic debridement is another option. Topical enzymes induce changes in the substrate, resulting in the breakdown of necrotic tissue (Ramundo & Wells, 2000). Depending on the type of enzyme used, the preparation either digests or dissolves tissue. Care must be taken to apply only to the wound bed, never periwound tissue.

► SKILL 46-2 Treating Pressure Ulcers

Delegation Considerations

The skill of treating pressure ulcers cannot be delegated to unregulated care providers (UCPs). In some practice settings, you can delegate *nonsterile* dressing application for chronic, established wounds when a nurse has evaluated and designated the protocol. The *assessment* of the wound remains within the scope of the nurse, however, even if the dressing change is delegated. Instruct nursing assistive personnel to do the following:

- Report changes in skin integrity to you immediately
- Report pain, fever, or wound drainage to you immediately
- Report any potential contamination to the existing dressing (e.g., patient incontinence or other bodily fluids; dressing becomes dislodged)

Procedure

STEPS

1. Assess patient's level of comfort using a scale of 1 to 10 and the need for pain medication.
2. Determine if patient has allergies to topical agents.
3. Review order for topical agent or dressing.
4. Close room door or bedside curtains. Position patient to allow dressing removal.
5. Perform hand hygiene, and apply clean gloves. Remove dressing, and place in plastic bag.
6. Assess pressure ulcer(s). All pressure ulcers need individual assessments (see Step 6 illustration).

Step 6 Measuring wound depth (steps b, c, and d.)

- A. Note colour, type, and percentage of tissue present in the wound base.
 - B. Measure width and length of the ulcer(s). Determine width by measuring the dimension from left to right and the length from top to bottom.
 - C. Measure depth of pressure ulcer using sterile cotton-tipped applicator (see Step 6 illustration).
 - D. Measure depth of undermining using sterile cotton-tipped applicator to gently probe under skin edges (see Step 6 illustration).
7. Assess periwound skin for maceration, redness, and denuded areas.
 8. Change to sterile gloves, if needed (check agency policy).

Equipment

- Disposable gloves (clean)
- Plastic bag for dressing disposal
- Disposable measuring tape
- Cotton-tipped applicators (sterile)
- Topical cleansing agent
- Dressing of choice (see Box 46-10)
- Hypoallergenic tape (if needed)
- Documentation record
- Measurement tool to record ongoing wound progress

RATIONALE

- Pain management enables better tolerance for dressing change.
- Topical agents cause localized skin reactions.
- Administration of proper medication and treatment is ensured.
- Privacy is provided; area is accessible for dressing change.
- Transmission of microorganisms is reduced; accidental exposure to body fluids is prevented.
- Consistent assessment will provide the basis for evaluating wound progress (RNAO, 2011).
- Determining tissue type assists in dressing selection.
- Ulcer size will change as healing progresses; therefore, longest and widest areas of the wound will change over time. Measuring width and length by measuring the same area will provide a consistent measurement (Nix, 2007).
- Depth is important to determine wound volume. Although surface area adequately represents tissue loss in stage II ulcers, volume more adequately represents tissue loss in stage III and IV wounds (RNAO, 2011).
- Undermining represents loss of underlying tissue (subcutaneous and muscle) to a greater extent than the skin. Undermining indicates progressive tissue loss.
- Deterioration of skin around a wound indicates infection, excessive wound exudate, or skin stripping from adhesive removal.
- Avoid potential contamination of wound from external source. Refer to institutional policy regarding use of clean or sterile gloves.

► SKILL 46-2 Treating Pressure Ulcers—cont'd

9. Cleanse ulcer thoroughly with normal saline or cleansing agent. Use irrigating syringe for deep ulcers.
 10. Apply topical agents, as prescribed:
 - A. Enzymes (where available)
 - (1) Apply thin, even layer of ointment over necrotic areas of ulcer only, where eschar has been scored if required. Protect periwound skin.
 - (2) Apply secondary nonadherent gauze dressing directly over ulcer.
 - (3) Tape securely in place.
 - B. Hydrogel
 - (1) Cover surface of ulcer with thin layer of hydrogel using applicator or gloved hand.
 - (2) Apply secondary nonadherent gauze dressing or transparent dressing over wound, and adhere to intact skin.
 - C. Calcium alginate or hydrofibre
 - (1) Lightly pack wound with alginate or hydrofibre using applicator or gloved fingers.
 - (2) Apply secondary dressing of nonadherent gauze, absorbent pad, or foam over alginate. Tape in place.
 11. Remove gloves, dispose of soiled supplies. Perform hand hygiene.
 12. Assess pressure ulcer at each dressing change or sooner if the wound or patient's condition deteriorates (Nix, 2007). Utilize agency's tool for wound assessment.
 13. Compare wound assessment to identified plan of care, and discuss with health care team if increase in size of wound, increased presence of pain, foul-smelling drainage, or increase in devitalized tissue.
- Wound debris must be removed to support healing tissue (RNAO, 2011).
 - A thick layer of ointment is not necessary; a thin layer absorbs and is more effective (Rolstad & Ovington, 2007). Check manufacturer's directions for frequency of application.
 - Wound is protected. Bacteria are prevented from entering wound.
 - Dressing is kept in place. Use tape or adhesive that will not irritate skin.
 - A moist wound environment is maintained.
 - Wound base is covered and hydrogel–wound interface is maintained.
 - Wound moisture is maintained while excess drainage is absorbed.
 - Alginate is held against wound surface.
 - Transmission of microorganisms is reduced.
 - Not all patients with wounds will follow healing trajectory due to comorbidities. Consistent assessment provides record of healing progress, deterioration, or stalled wound.
 - Wound care is an interdisciplinary activity and requires involvement of the team of health care providers as well as patient and family.

Critical Decision Point: A clean pressure ulcer should show evidence of some healing within two to four weeks. Do *not* use the pressure ulcer staging system to measure pressure ulcer healing. The system measures depth of wound, not healing (WOCN, 2003).

14. Complete wound documentation required for one of the wound assessment instruments per agency's protocol.
- Assessments compared over time will determine progress toward wound healing.

Unexpected Outcomes

Maceration of skin surrounding ulcer

Deepening of ulcer and increased drainage

Related Interventions

- Reduce exposure of surrounding skin to topical agents and moisture.
- Consider use of a skin barrier on periwound skin.
- Use a dressing that will wick exudate away from periwound skin.
- Notify health care team re: possible wound infection.
- Obtain necessary wound cultures.
- Obtain additional consults (e.g., wound care specialist).

Recording and Reporting

- Record assessment of ulcer in patient's record.
- Describe type of topical agent used, dressing applied, and patient's response.
- Report any deterioration in ulcer appearance.

Home Care Considerations

- Assess ability of patient or family to manage dressing changes and provide education and support.
- Patients need to dispose of contaminated dressings in the home in a manner consistent with local regulations (WOCN, 2003).
- Discuss need for a home pressure-redistribution surface or bed.

Current best practice treatment options are autolytic and sharp or surgical debridement (the "gold standard"). Autolytic debridement uses synthetic dressings over a wound to allow the eschar and fibrinous slough within the wound to be self-digested by the action of enzymes that are present in wound fluids (CAWC, 2006). Dressings that support moisture at the wound surface (e.g., hydrogel or hydrocolloid) maintain a moist wound bed ("moist like your eyeball"), which allows the movement of epithelial cells and facilitates wound closure; however, a wound that has excessive exudate (drainage) provides an environment that supports bacterial growth, macerates the periwound skin, and slows the healing process (CAWC, 2006). If exudate is excessive, use an absorptive dressing (e.g., calcium alginate, hydrofibre, or foam) and evaluate volume, consistency, and odour of drainage to determine whether infection may be present.

Sharp or surgical debridement is the most efficient way to reach vitalized tissue at the base of a wound and is also used when sepsis can be localized and excised. Surgical debridement with a scalpel, scissors, or other sharp instrument should be performed only by those health care providers with knowledge, skill, and competence to perform the procedure, usually physicians and advanced practice nurses (e.g., nurse practitioners). Your regulating authority (e.g., College of Nurses) and your agency or institution policy mandates whether you are able to perform sharp or surgical debridement.

Remember, the wound will not heal, regardless of the use of topical therapy (Rolstad & Ovington, 2007), unless you control or eliminate the causative factors (e.g., malnourishment, shear, friction, pressure, and moisture). In addition, as the wound goes through the phases of healing, you will need to alter the treatment plan. For example, in the management of a necrotic and sloughy wound, you may initially use a hydrocolloid dressing to autolytically debride the wound. Because this process takes time, leave the dressing intact for up to one week. Once the wound is cleansed of necrotic, fibrinous tissue, you will discontinue the hydrocolloid dressing and choose another dressing after assessing the wound base characteristics. Continued reassessment is key to supporting the wound as it moves through the phases of wound healing. It cannot be stressed enough how important it is for you to explain the process of wound healing to the patient and family.

Growth Factors. Growth factors regulate most of the key actions of cells during wound healing, and topical growth factors regulate the healing of chronic wounds (Schultz, 2007). Through extensive studies of the molecular regulation of healing, researchers now better understand the role of various growth factors involved in wound healing, including epidermal growth factor, platelet-derived growth factor, fibroblast growth factor, and transforming growth factor. Depending on the setting, you may be responsible for the use of this treatment modality.

Nutritional Status. Nutritional assessment and support of the patient with a wound is a key component in normal cellular integrity and tissue repair (Stotts, 2007a). You need to correct inadequate nutrition and support healing through early intervention. The Joint Commission (2007) recommends nutritional assessment within 24 hours of admission. Assess the patient's mouth and skin for signs of nutritional deficiencies (see Chapter 42). Reassessments reflect changes in status and effects of interventions (Stotts, 2007a). Box 46-12 defines parameters for clinically significant malnutrition (AHCPR, 1994).

> BOX 46-12

AHCPR* Recommendations for Nutritional Assessment and Management of Pressure Ulcers

Assessment of Clinically Significant Malnutrition

Serum albumin is less than 3.5 mg/100 mL.
Total lymphocyte count is less than 1800/mm³.
Body weight has decreased more than 15%.

Interventions

- Involve dietitian to prevent malnutrition and ensure adequate dietary intake.
- Maintain serum albumin level greater than 3.5 mg/100 mL.
- Maintain total lymphocyte count greater than 1800/mm³.
- Perform an abbreviated nutritional assessment, according to institutional policy and as defined by the Nutritional Screening Initiative, at least every three months for patients who are unable to take food by mouth or who experience an involuntary change in weight.
- Encourage dietary intake or supplementation if a patient with a pressure ulcer is malnourished. If dietary intake continues to be inadequate, impractical, or impossible, use nutritional support (usually tube feeding) to place the patient into positive nitrogen balance (approximately 30 to 35 calories/kg/day and 1.25 to 1.50 g of protein/kg/day) according to the goals of care.
- Give vitamin and mineral supplements if you suspect or confirm deficiencies.

*AHCPR, Agency for Health Care Policy and Research.

Source: Adapted from Agency for Health Care Policy and Research, Panel for Treatment of Pressure Ulcers in Adults. (1994). *Treatment of pressure ulcers: Clinical practice guideline no. 15*. (AHCPR Pub No. 95-0653). Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services.

Protein Status. Patients with a potential for or actual decreased serum albumin levels or poor protein intake need a nutritional evaluation to ensure proper caloric intake (AHCPR, 1994). A patient can lose as much as 50 g of protein per day from an open, weeping pressure ulcer. Although the recommended intake of protein for adults is 0.8 g/kg/day, a higher intake of protein up to 1.8 g/kg/day is necessary for healing. Increased protein intake helps rebuild epidermal tissue. Increased caloric intake helps replace subcutaneous tissue. Vitamin C promotes collagen synthesis, capillary wall integrity, fibroblast function, and immunological function.

Hemoglobin. A low hemoglobin level decreases delivery of oxygen to the tissues and leads to further ischemia. When possible, maintain hemoglobin at 12 g/100 mL.

Dressings

For surgical wounds that heal by primary intention, it is common to remove dressings as soon as drainage stops. In contrast, when a wound is healing by secondary intention, the dressing material becomes a means for providing an optimal healing environment.

Purposes of Dressings. A dressing serves several purposes:

- Protects wound from microorganism contamination
- Aids in hemostasis
- Promotes healing by absorbing drainage and supports autolytic debridement

- Supports or splints the wound site
- Protects the patient from seeing the wound (if perceived as unpleasant)
- Promotes thermal insulation of the wound surface
- Provides a moist environment for the wound bed

In a normally healing wound, when wound drainage is minimal, the healing process forms a natural fibrin seal that eliminates the need for a dressing. Wounds with extensive tissue loss always need a dressing.

A pressure dressing is applied with elastic bandages, exerts localized downward pressure over an actual or potential bleeding site, and eliminates dead space in underlying tissues so that wound healing progresses normally. Check pressure dressings to be sure that they do not interfere with circulation to a body part. Assess skin colour, pulses in distal extremities, the patient's comfort, and changes in sensation. Pressure dressings are not routinely removed.

Specific dressings cover and protect certain types of wounds, such as large wounds, wounds with drainage tubes or suction catheters in the wound, wounds that need frequent changing, and fistulas. For these wounds, pouches or special wound collection systems cover the wound and collect wound drainage. Some of these devices have a plastic flange on the front of the wound pouch, which allows you to change wound packing without removing the wound pouch from the skin.

Understanding the method of action and purpose of the dressing selection facilitates wound healing (Rolstad & Ovington, 2007). When you identify the objectives for care of the wound, the dressing choice becomes clear. For example, a wound requiring exudate management requires a different type of dressing than one that requires debridement.

A primary function of a dressing on a healing wound is to protect the fragile wound bed. Most traditional surgical dressings have three layers: a contact or primary layer, an absorbent layer, and an outer protective or secondary layer. The contact dressing covers the incision and part of the adjacent skin. Fibrin, blood products, and debris adhere to the contact dressing's surface. A dressing that does not adhere to the wound bed, such as a Telfa pad or soft silicone, will not cause the dressing to stick to the suture line. Use of dry gauze or improper removal of the dressing will disrupt the healing epidermal surface. If a dressing sticks to the surgical incision, the dressing needs to be saturated with saline solution to release it from the incisional area and prevent trauma to the wound bed.

Types of Dressings. Wet-to-dry and wet-to-moist dressings are still often ordered, despite extensive research literature over the past 40 years that has clearly identified *moist wound healing* as being the most appropriate, in most situations, to manage wounds and support healing within the wound. As clinical researchers develop more appropriate dressings, it is essential that you understand the reason why wet-to-dry and wet-to-moist dressings are neither current best practice, nor supported in the research literature.

The basic premise behind the wet-to-dry dressing is to put a wet dressing (gauze and normal saline) on a wound, allow it to dry out, and then pull off the now-dry dressing, thereby mechanically debriding the wound. This is not effective, however, since the action is nonselective, so healthy granulating tissue is removed along with any necrotic or sloughy tissue. In addition, this type of action is inevitably painful to the patient; given the current availability of nontraumatic dressings, this seems an unnecessary condition for patient care.

Wet-to-moist dressings are the use of a saline-soaked gauze that is not left to dry out on the wound, but rather kept moist on the wound through frequent dressing changes. Research has shown that frequency of dressing changes has a negative impact on wound healing (the disruption of fragile granulation tissue, cooling down the wound bed, etc.). As well, the dressing that is moistened with normal saline becomes a hypertonic environment that pulls fluid out of the wound bed in a way that leaves a slurry of blood and proteins on the surface of the wound, which, if not kept constantly moist, dries out (becoming a wet-to-dry dressing).

However, since these approaches are still used in some situations, you do need to know the steps to follow when applying this type of dressing to a wound. It is strongly recommended that you consider alternatives (and there are many) to this approach, since it is not particularly effective in promoting wound healing. You are encouraged to discuss the rationale for moist wound healing for the patient in question with the other care providers, in order to support evidence-informed best practices (Ovington, 2001).

Dressings vary by type of material and mode of application (wet or dry) (Skill 46-3). They need to be easy to apply, comfortable, and made of materials that promote wound healing. The RNAO guidelines (2011) should help you select dressings that respond to the need of the wound, based on the goal for the wound: to heal, to protect from infection, to provide comfort, or to maintain current status (nonhealing wound). A dressing designed to wick away exudate and avoid skin stripping from adhesives will protect the periwound skin. Protecting the wound bed requires a dressing that will maintain a moist wound bed (not too dry, not too wet), prevent contamination from external sources such as feces or urine, and be conformable to the wound and surrounding tissue (Box 46-13; see also Table 46-9). In addition, if the wound is deep, undermining, or has tunnelling or sinus tracts, ensure that no dead space remains to create an opportunity for an abscess to develop. In this situation, lightly pack the wound with appropriate dressing material (i.e., nonwoven gauze moistened with hydrogel in a dry wound, hypertonic sodium ribbon in a wet or contaminated wound, and silver or cadexomer iodine packing in an infected wound [Sibbald, Orsted, et al., 2006]).

► BOX 46-13

WOCN* Dressing Recommendations

- Use a dressing that will continuously provide a moist ("like your eyeball") environment. Wet-to-dry dressings should be avoided.
- Perform wound care using topical dressings as determined by a thorough assessment. No specific studies have proven an optimal dressing type for pressure ulcers.
- Choose a dressing that keeps the surrounding intact (periulcer) skin dry while keeping the ulcer bed moist.
- Choose a dressing that controls exudate but does not desiccate the ulcer bed.
- Consider caregiver time, ease of use, availability, and cost when selecting a dressing.
- Eliminate wound dead space by loosely filling all cavities with dressing material.

*WOCN, Wound, ostomy, and continence nurses.

► SKILL 46-3 Applying Dry and Moist Dressings

Delegation Considerations

The skill of applying dry and moist dressings to the new acute wound cannot be delegated to unregulated care providers (UCPs). In some settings, you can delegate aspects of wound care, such as changing of dressings using *clean* techniques for chronic wounds. The *assessment* of the wound remains within the scope of the nurse, however, even if the dressing change is delegated. Instruct nursing assistive personnel to do the following:

- Report pain, fever, bleeding, or wound drainage to you immediately
- Report any potential contamination to the existing dressing (e.g., patient incontinence or other bodily fluids; dressing becomes dislodged)

Procedure

STEPS

1. Perform hand hygiene. Obtain information about size and location of wound.
2. Assess patient's level of comfort.
3. Review orders for dressing change procedure.
4. Explain procedure to patient, and instruct patient not to touch wound area or sterile supplies.
5. Close room or cubicle curtains and windows.
6. Position patient comfortably, drape with bath blanket to expose only wound site.
7. Place disposable bag within reach of work area. Fold top of bag to make cuff (see Step 7 illustration).

Step 7 Disposable waterproof bag placed near the dressing site.

8. Apply face mask and protective eyewear, if needed.
9. Put on clean, disposable gloves; remove tape, bandage, or ties.
10. Remove tape: pull parallel to skin toward dressing; remove remaining adhesive from skin.
11. With gloved hand, carefully remove gauze dressings one layer at a time, taking care not to dislodge drains or tubes.

Equipment

- Sterile gloves
- Variety of gauze dressings and pads
- Irrigation kit
- Cleansing solution
- Sterile solution
- Clean, disposable gloves
- Tape, ties, or bandages, as needed
- Waterproof bag
- Extra gauze dressings, or abdominal pads

RATIONALE

- Transmission of microorganisms is reduced. Plan for proper type and amount of supplies needed. Know when assistance is needed to hold dressings in place.
- Removal of a dry dressing is painful; some patients require pain medication.
- Orders indicate type of dressing or applications to use.
- Explanation decreases anxiety. Sudden, unexpected movement on patient's part will result in contamination of wound and supplies.
- Privacy is provided; airborne microorganisms are reduced.
- Wound is accessible; unnecessary exposure is minimized.
- Soiled dressings can easily be disposed of. Bag's outer surface is not soiled.

- Transmission of pathogens to exposed tissues is reduced. Mask and eyewear protects from splashes.
- Transmission of infectious organisms from soiled dressings to hands is prevented.
- Pulling tape toward dressing reduces stress on suture line or wound edges.
- Appearance of drainage is sometimes upsetting to patient. Removal of one layer at a time reduces the chance of accidental removal of underlying drains.

► SKILL 46-3 Applying Dry and Moist Dressings—cont'd

- A. If dressing sticks on a wet-to-dry dressing, do not moisten it; instead gently free dressing, and alert patient of potential discomfort.
- Wet-to-dry dressing should debride wound (Ramundo & Wells, 2000). Do not wet the dressing to remove it. However, re-assess and select other method of debridement.

Critical Decision Point: Never use a wet-to-dry dressing in a clean granulating wound. Use only for debridement and only if other debridement options are unavailable (Ramundo, 2007).

12. Observe character and amount of drainage on dressing and appearance of wound.
13. Fold dressings with drainage contained inside, and remove gloves inside out. With small dressings, remove gloves inside out over dressing (see Step 13 illustration). Dispose of gloves and soiled dressings in disposable bag. Perform hand hygiene.
14. Open sterile dressing tray or individually wrapped sterile supplies. Place on bedside table (see Step 14 illustration).
- Estimate of drainage amount and appearance of wound assist in determining progress.
- Transmission of microorganisms is reduced. Hands do not come into contact with material on gloves.
- Sterile dressings remain sterile while on or within sterile surface. Preparation of supplies prevents break in technique during dressing change.

Step 13 Removal of disposable gloves over contaminated dressing.

Step 14 Sterile dressing equipment.

15. If ordered, cleanse or irrigate wound:
 - A. Pour ordered solution into sterile irrigation container.
 - B. Using syringe, gently allow solution to flow over wound.
 - C. Continue until the irrigation flow is clear.
 - D. Dry surrounding skin.

Critical Decision Point: Some wound cleansers are available in spray bottles. Spray to loosen debris.

16. Apply dressing:
 - A. Dry dressing
 - (1) Apply sterile gloves.
 - (2) Inspect wound for appearance, drains, drainage, and integrity.
 - (3) Cleanse wound with solution:
 - (a) Clean from least-contaminated area to most-contaminated area.
 - (4) Dry area.
 - (5) Apply sterile, dry dressing covering wound.
 - (6) Apply topper (cover) dressing if indicated.
 - B. Moist dressing
 - (1) Apply clean gloves.
 - (2) Remove old dressings, discard.
- Sterile supplies can be handled without contamination.
- Wound healing status is indicated.
- Contamination of previously cleaned area is prevented.
- Protection and absorption of wound drainage is provided.
- Wound is protected from external environment.
- Topper dressing prevents strikethrough of wound drainage and provides a surface to tape the dressing in place.

Continued

► SKILL 46-3 Applying Dry and Moist Dressings—cont'd

- (3) Assess surrounding skin (see Step 16B[3] illustration). Discard gloves.

Step 16B(3) Exposure of wound facilitates assessment of wound and surrounding skin.

- (4) Apply sterile gloves.
 (5) Cleanse wound base with normal saline or commercially prepared wound cleanser. Assess wound base.
 (6) Moisten gauze with prescribed solution. Gently wring out excess solution. Unfold.
 (7) Apply gauze as a single layer (see Step 16B[7] illustration) directly onto the wound surface. If wound is deep, gently pack dressing into wound base by hand or with forceps until all wound surfaces are in contact with the gauze. If tunnelling is present, use a cotton-tipped applicator to place gauze into tunnelled area. Be sure gauze does not touch the surrounding skin (see Step 16B[7] illustration).

- Surrounding skin assessment provides an evaluation of wound management.

Step 16B(7) Packing wound with single layer of gauze.

- (8) Cover with sterile dry gauze and topper dressing.

17. Secure dressing.

A. Tape: Apply nonallergenic tape to secure dressing in place.

B. Montgomery ties (see Figure 46-23 on p. 1290)

- (1) Expose adhesive surface of tape on end of each tie.
 (2) Place ties on opposite sides of dressing.
 (3) Place adhesive directly on skin, or use skin barrier.

- Handling of sterile supplies can occur without contamination.
- Cleansing removes wound debris for adequate assessment.
- Gauze needs to be moist to allow for absorption of wound debris.
- Inner gauze needs to be moist, not dripping wet, to absorb drainage and adhere to debris. Excessively moist dressings result in moisture-associated skin damage (maceration) in the periwound skin (Gray & Weir, 2007). The wound needs to be loosely packed to facilitate wicking of drainage into absorbent outer layer of dressing.
- Topper dressing prevents strikethrough of wound drainage and provides a surface to tape the dressing in place.
- The goal for securing a dressing is to keep the dressing in place and intact without causing damage to underlying and surrounding skin.
- Protects periwound skin from breakdown through frequent dressing changes.
- Skin barrier (Stomahesive) protects intact skin from stretch and tension of adhesive tape.

► SKILL 46-3 Applying Dry and Moist Dressings—cont'd

- C. For dressings on an extremity, secure dressing with rolled gauze or an elastic net (see Step 17C illustration)

Step 17C Elastic net securing a lower extremity dressing.

18. Remove gloves, and dispose of in bag. Remove any mask or eyewear.
19. Dispose of supplies, and perform hand hygiene.
20. Assist patient to comfortable position.

- Transmission of infection is reduced.
- Transmission of infection is reduced.
- Patient's sense of well-being is promoted. Comfort is enhanced.

Unexpected Outcomes

Wound appears inflamed, tender, with or without drainage

Wound drainage increases

Wound bleeds during dressing change

Sensation that "something has given way under the dressing"

Related Interventions

- Monitor patient for signs of infection (e.g., increased temperature or white blood cell count).
- Obtain wound culture.
- Notify health care provider.
- Increase frequency of dressing changes.
- Notify health care provider, who may consider drain placement to facilitate wound drainage.
- Observe colour. If drainage is bright red and excessive, you will need to apply pressure.
- Inspect along dressing and underneath patient to determine amount of bleeding.
- Obtain vital signs, as needed.
- Notify health care provider.
- Observe wound for increased drainage or separation of sutures.
- Protect wound. Cover with sterile moist dressing.
- Instruct patient to lie still.
- Notify health care provider.

Recording and Reporting

- Report brisk, bright-red bleeding or evidence of wound dehiscence or evisceration to health care provider immediately.
- Report wound and periwound tissue appearance, colour, and tissue type and presence and characteristics of exudate, type and amount of dressings used, and tolerance of patient to procedure.
- Record patient's level of comfort.
- Write date and time dressing applied on tape in ink (not marker).

Home Care Considerations

- More expensive specialty dressings are sometimes used because they decrease the frequency of dressing changes.
- Assess ability of patient and family to manage dressing changes independently.
- Patients need to dispose of contaminated dressings in the home in a manner consistent with local regulations.

Woven Gauze Dressings. In the past, woven gauze dressings were commonly used to provide coverage for wounds; however, research has demonstrated their efficacy in wound healing is limited (CAWC, 2006). Providing the opportunity for a noninfected wound to heal using "moist wound healing" approaches and dressings does limit the use of gauze as an effective dressing. However, nonwoven gauze remains useful as packing material (e.g., Nu-gauze). Gauze is available

in different textures and in various lengths and sizes; the 4 × 4 is the most common. Gauze can be saturated with solutions and used to cleanse and pack a wound. When used to pack a dry wound, the gauze should be lightly moistened with hydrogel (see p. 1287) to provide moisture to the wound bed. Use nonadherent gauze dressings such as Telfa over clean wounds with little or no drainage. Telfa gauze has a shiny, nonadherent surface that does not stick to incisions or wound openings but

► TABLE 46-9 Wound Care Dressings

	Class	Description	Local Wound Care*			Care Considerations
			Tissue Debridement	Infection	Moisture Balance	
1. Films and membranes		Semipermeable adhesive sheet. Impermeable to H ₂ O molecules and bacteria	+	–	–	Moisture vapour transmission rate varies from film to film. Should not be used on draining or infected wounds.* Create occlusive barrier against infection.
2. Nonadherent contact layer		Sheets of low adherence to tissue. Nonmedicated tulle, silicone, and petrolatum-based woven dressings.	–	–	–	Allow drainage to seep through pores to secondary dressing and evaporate off the wound. Require a cover (absorbent) dressing.
3. Hydrogels		Polymers with high H ₂ O content. Available in gels, solid sheets, or impregnated gauze	++	–	+	Should not be used on draining wounds. Solid sheets should not be used on infected wounds.
4. Hydrocolloids		May contain gelatin, sodium, carboxymethylcellulose, polysaccharides, or pectin, or a combination of these. Sheet dressings are occlusive and have polyurethane film outer layer	+++	+/-	++	Should be used with care on fragile skin. Should not be used on heavily draining or infected wounds.* Create occlusive barrier to protect the wound from outside contamination. Characteristic odour may accompany dressing change and should not be confused with infection.
5. Calcium alginates		Sheets or fibrous ropes of calcium sodium alginate (seaweed derivative). Have hemostatic capabilities	++	+	+++	Should not be used on dry wounds. Avoid packing into narrow deep sinuses because of low tensile strength. Bioreabsorbable.
6. Composite dressings		Multilayered, combination dressings to increase absorbency and autolysis	+	–	+++	Use on wounds on which dressing may stay in place for several days.*
7. Foams		Nonadhesive or adhesive polyurethane foam. May have occlusive backing. Sheets or cavity packing. Some have fluid lock.	–	–	+++	Use on moderate to heavily draining wounds. Occlusive foams should not be used on heavily draining or infected wounds.*
8. Charcoal		Contains odour-absorbent charcoal within product	–	–	+	Some charcoal products are inactivated by moisture. Ensure that dressing edges are sealed.
9. Hypertonic		Sheet, ribbon, or gel impregnated with sodium concentrate.	+	+	++	Gauze ribbon should not be used on dry wounds. May be painful on sensitive tissue. Gel may be used on dry wounds.
10. Hydrophilic fibres		Sheet or packing strip of sodium carboxymethyl-cellulose. Converts to a solid gel when activated by moisture (fluid lock).	+	–	+++	Best for moderate amount of exudate. Should not be used on dry wounds. Avoid packing into narrow deep sinuses because of low tensile strength.
11. Antimicrobials		Medical grade honey, silver, cadexomer iodine with vehicle for delivery: sheets, gels, alginates, foams, or paste	+	+++	+	Broad spectrum against bacteria. Not to be used on patients with known hypersensitivities to any product components.

*"+ " indicates the appropriateness of the dressing for tissue debridement, infection, and moisture balance. "–" indicates the dressing is not considered beneficial in these areas. Use with caution if critical colonization is suspected.

► TABLE 46-9 Wound Care Dressings—cont'd

	Class	Local Wound Care*			Care Considerations
12. Other devices	NPWT applies localized negative pressure to surface and margins of wound. Dressings consist of polyurethane or polyvinyl alcohol materials.	—	+	+++	Pressure-distributing wound dressing actively removes fluid from the wound and promotes wound edge approximation. Advanced skill required for patient selection for this therapy.
13. Biological	Living human fibroblasts provided in sheets at ambient or frozen temperatures. Extracellular matrix. Collagen-containing preparations. Hyaluronic acid. Platelet-derived growth factor.	—	—	—	Should not be used on wounds with infection, sinus tracts, excessive exudate, or on patients known to have hypersensitivity to any of the product components. Cultural issues related to source. Advanced skill required for patient selection for this therapy.

allows drainage to pass through to the gauze topper. Acute surgical wounds are most likely to be packed with saline-moistened nonwoven gauze and the dressing changed at frequent intervals, usually determined by the surgeon.

Transparent Film Dressings. Self-adhesive, transparent film dressings are occlusive and trap the wound's moisture over the wound, providing a moist environment. The transparent film dressing has been used for small, superficial wounds such as skin tears or for protection of high-risk skin. However, transparent film dressings can be difficult to remove and can cause unnecessary trauma to fragile periwound tissue. You must remove the transparent film with a "lateral pull" technique, in which you support the dressing with one hand while lifting (and breaking the adhesive seal) with the other, instead of just pulling off the dressing. Bearing these factors in mind, you can use transparent film dressing to affix gauze, and it can also function as a secondary dressing or provide autolysis for small wounds.

However, transparent film is particularly useful in securing IVs and other tubing since these dressings tend to provide an occlusive barrier, which does not allow significant moisture-vapour transfer and can potentially create macerated periwound skin.

Transparent film does permit a view of the wound, but some newer dressings, such as clear acrylic absorbent dressings, offer more moisture-vapour transfer capability and longer wear time.

Nonadherent Contact Layer Dressings. A variety of nonadherent dressings is available and provide protection to the fragile granulating tissue while allowing the interstitial fluid and moisture from the wound to evaporate. This provides a moist "like your eyeball" environment that promotes healing. As well, the contact layer can remain undisturbed while a secondary cover dressing can be changed as needed (when saturated or soiled). Early forms of contact layer dressings were tulle (paraffin) or petrolatum jelly, which may decrease the effectiveness of moisture-vapour transfer. Some of the newer petrolatum-based or silicone contact layers are more effective in this regard. These dressings are designed to be placed over the open wound and draped across the intact periwound skin. It is important for wound healing to allow these contact layer dressings to remain in place for a number of days, and change the secondary dressing only as needed.

Soft Silicone Dressings. Soft silicone dressings are composed of silicone that functions as an atraumatic wound contact layer. A main advantage of soft silicone is its removal without causing trauma to the wound bed or the periwound skin. Different types of soft silicone dressings are wound contact layers (useful for skin tears) and absorbent dressings for exudating wounds. Soft silicone dressings are particularly relevant in decreasing pain during dressing change and are especially useful in dealing with fungating wounds or any wound where the periwound skin is fragile, such as in pediatric patients.

Hydrocolloid Dressings. Hydrocolloid dressings have complex formulations of colloidal, elastomeric, and adhesive components. These dressings are adhesive and occlusive. The wound contact layer of the dressing forms a gel as fluid is absorbed and maintains a moist healing environment. Hydrocolloids support healing in clean granulating wounds, autolytically debride necrotic wounds, and are available in a variety of sizes and shapes.

Hydrocolloid dressing has the following characteristics:

- Has minimal absorption capabilities and is best for autolytically debriding a dry or slightly moist wound with fibrinous or necrotic debris
- Maintains wound bed moisture
- Slowly liquefies necrotic debris
- Is impermeable to external bacteria and other contaminants
- Is self-adhesive and conforms to the body well
- Acts as a preventive dressing for high-risk friction areas
- May be left in place for five to seven days

This type of dressing is most useful on shallow to moderately deep wounds. Hydrocolloid dressings should not be used in heavily draining wounds or in full-thickness or infected wounds. Because of the manner in which hydrocolloids interact with the wound bed matter, when the dressing is removed, residue in the wound bed may be confused with pus (colour, odour) until the wound is cleansed. Hydrocolloids are quite adherent to the periwound skin and should be used with caution where the periwound tissue is fragile or friable.

Hydrogel Dressings. Hydrogel dressings donate moisture to the wound bed (hence, the term *hydro*, indicating water) and are gauze or sheet dressings impregnated with water- or glycerin-based amorphous gel. This type of dressing hydrates

wounds and absorbs some smaller amounts of exudate. Hydrogel dressings are for partial-thickness and full-thickness wounds, deep wounds with minimal drainage, necrotic wounds, burns, and radiation-damaged skin. They are very useful in painful wounds because they are soothing to the patient, do not adhere to the wound bed, and cause minimal trauma during dressing removal. Hydrogels should not be used on draining wounds; sheets should not be used on infected wounds. Hydrogels come in a sheet dressing or in a tube. When using hydrogel from a tube, do not squirt gel directly into the wound; rather, use a sterile gauze dressing or sterile implement (e.g., tongue depressor) to apply the gel so that potential contamination of the tube from matter in the wound is avoided.

Hydrogel has the following characteristics:

- Is soothing and reduces pain in the wound
- Provides a moist environment
- Debrides the wound (by softening the necrotic tissue)
- Does not adhere to the wound base and is easy to remove

Foam Dressings. Foam dressings are composed of non-adhesive or adhesive polyurethane foam, are provided as sheets or packing, and come in a variety of sizes and shapes. They are useful for wounds with large amounts of drainage or for autolytic debridement because they can be left intact for up to seven days. Some foam dressings have a “fluid lock” to wick drainage off the wound and periwound skin, which prevents maceration. Furthermore, nonborder foam dressings can be cut to fit around drainage tubes.

Calcium Alginate Dressings. Calcium alginate dressings are manufactured from seaweed and are available in sheet and rope form. The alginate forms a thickened, stronger surface when it comes in contact with wound fluid. These highly absorbent dressings are useful in highly draining wounds and also provide hemostasis in friable tissue. Calcium alginate dressings are bioreabsorbable but should be removed from the wound.

Another type of dressing very useful for highly exudative wounds is hydrofibres, composed of sodium carboxymethylcellulose. These are available in sheets or ribbon and are used in similar situations to the calcium alginates. The main advantage of the hydrofibre dressing is that when exposed to fluid, it becomes a solid gel. This is particularly useful when the wound bed or wound edge is friable, for example, in malignant fungating wounds.

Neither of these dressings should be used on or in dry wounds. Secondary dressing (usually some form of absorbent pad) is required.

Composite Dressings. Composite dressings are a combination of two different dressing types. These multilayered dressings are designed to provide both absorption and autolysis. Composite dressings can remain in place for up to three days.

Topical Treatment for Infected Wounds. Superficially infected wounds require topical dressings to deal with the bacteria within the wound and surrounding tissue. Deep tissue infection requires the addition of antibiotic therapy, which can be determined from wound swab cultures (Sibbald, Woo, et al., 2006). Topical dressings range from hypertonic sodium solutions to silver antimicrobials.

Hypertonic Dressings. Hypertonic dressings contain a high concentration of sodium, which pulls out interstitial fluid, decreases edema to improve blood flow to the tissue surrounding the wound, and establishes a negative environment for bacterial growth. These dressings are available in ribbon, sheet,

or gel form. Some patients find that the hypertonic dressings sting, and they should be changed once a day. Carefully monitor dressings with active ingredients on a daily basis.

Cadexomer Iodine. Cadexomer iodine dressings are available in sheets or a tube and provide the toxicity of iodine in a starch matrix. The iodine downloads into the wound bed in a controlled fashion, targeting only bacteria. The colour change of the dressing indicates its efficacy: it is brown when you apply it and gradually changes to cream-coloured as the iodine is absorbed. This process usually takes 72 hours, so the dressing should be left intact for three days. Changing the dressing more frequently will interfere with the effectiveness of the product. Use large amounts of cadexomer iodine with caution (see product monograph for limits), and do not use in breastfeeding women or patients with thyroid conditions.

Silver Dressings. Silver dressings have antimicrobial effects similar to cadexomer iodine, against approximately 150 different pathogens, including fungal infections, methicillin-resistant *Staphylococcus aureus* (MRSA), and vancomycin-resistant enterococci (VRE). You can use silver dressings in sheet, ribbon, rope, woven, and foam formats in a variety of sizes. The amount of silver in the dressing, which affects the kill rate (speed and sustainability), varies, and silver dressings require moisture to become activated—either from the wound bed exudate or with the use of a scant amount of hydrogel laid down in the base of the wound first. In addition, most silver dressings will require a secondary dressing, and their efficacy ranges from three to seven days, depending on the product. No sensitivity to silver dressings has been reported, but patients do occasionally complain of stinging as the silver is activated. Be aware that some forms of silver dressings may leave a black stain around the periwound skin.

Honey (Medical Grade Leptospermum Honey). Honey has long been known to have antimicrobial properties. As a treatment option for infected or suspected infection in wounds, it is particularly effective as it changes the pH in the wound bed, creating a negative environment for bacterial proliferation and produces a low concentration of hydrogen peroxide, which does not damage the healing tissue. As well as killing bacteria (e.g., MRSA and VRE), it has a significant impact on decreasing wound odour. The medical grade format of Manuka honey is available in a variety of formats. It is particularly useful in pilonidal cysts as it can be applied in a warmed liquefied format directly into the wound, with a hydrofibre and simple cover dressing. The wound can be irrigated and more of the medical grade honey introduced to the wound. Often wounds treated with honey will have an increase in drainage initially and may require more frequent dressing changes.

Negative Pressure Wound Therapy. Negative pressure wound therapy (NPWT) is another modality for dressings. The approach uses a machine that applies localized negative pressure to the surface and margins of the wound, pulling up the base of the wound and enhancing healing rates. It can be very effective, particularly in wounds in which rapid healing is viable, and will enhance patients' quality of life. Although expensive, the method, in the appropriate situation, can significantly increase wound healing, thus decreasing the requirement for health care resources, including hospitalization. Usually these dressings are changed three times a week.

NPWT is also used to enhance the viability of split-thickness skin grafts. Placing it over the graft intraoperatively decreases the ability of the graft to shift and evacuates fluids that build up under the graft (Frantz et al., 2007).

Changing Dressings. When changing a dressing, keep in mind that the characteristics of the wound may have changed. However, be prepared with similar dressings as previously used and know the location of underlying drains or tubing and the type of supplies needed for care of the wound. Poor preparation can result in a break in aseptic technique (see Chapter 32), accidental dislodging of a drain, or unnecessary discomfort to the patient as you search for supplies.

Your judgement in modifying a dressing change procedure is important during wound care. If the character of a wound changes, notify the physician or wound care specialist. Ensure open and clear communication with the physician or advanced practice nurse who documents your interventions, even though you do not require a medical order to change a dressing. If an order is written, it is your responsibility to assess the current status of the wound in relation to the order. Has the wound changed? Would a different dressing be more effective? You will need to communicate this to the physician or advanced practice nurse.

An order to “reinforce dressing prn” (add dressings without removing the original one) is common immediately after surgery, when the surgeon does not want accidental disruption of the suture line or bleeding. The medical or operating room record usually indicates whether drains are present and from what body cavity they drain. After the first dressing change, describe the location of drains and the type of dressing materials and solutions to use in the patient’s care plan.

Clean or Sterile Technique. The body of literature about sterile versus clean dressing techniques is growing. The RNAO guidelines (2011) recommend sterile dressings, good hand-washing, and clean gloves changed between each of the patient’s wounds or when soiled. For surgical wounds, preliminary research indicates no difference in the healing rate of wounds when a clean rather than a sterile dressing change technique is used. Although aseptic or sterile technique is often used for surgical wound care, the most important aspects of this approach are to ensure as clean a field as possible with the use of sterile dressing packs, sterile scissors and forceps, and sterile dressings and gloves.

Preparing for Dressing Change (in Any Care Setting). To prepare a patient for a dressing change, do the following:

- Administer required analgesics so that peak effects occur during the dressing change
- Describe steps of the procedure to lessen patient anxiety
- Gather all supplies required for the dressing change
- Recognize normal signs of healing
- Answer questions about the procedure or the wound

Always consider teaching the patient and family how to change the dressing, particularly in the home care setting. Demonstrate dressing changes to the patient and family and then provide an opportunity for them to practise changing a dressing when you are present. In acute care, by the time the patient is ready to be discharged, wound healing has usually progressed past the point when complications such as dehiscence or evisceration might occur. The AHCPR guidelines (1994) regarding clean dressings in the home setting and disposal of contaminated dressings in the home can be found in Skill 46-3 (shown earlier), which outlines the steps for changing dry and moist dressings.

Packing a Wound. When packing a wound, first assess the size, depth, and shape of the wound, then assess for tunnelling and undermining of the wound. These wound

characteristics will help you determine the size and type of dressing material needed to pack the wound. Many dressing materials, such as alginates, are used to pack wounds. If non-woven gauze is the appropriate dressing material, saturate the gauze with the ordered solution, wring it out, unfold it, and lightly pack it into the wound. The entire wound surface needs to be in contact with part of the moist gauze dressing (see Skill 46-3). As stated in the RNAO guidelines (2011), “keeping the wound moist and the surrounding intact skin dry” (p. 43) will prevent maceration and help maintain a moist wound environment, and when using a dressing “loosely pack any sinus tract or cavity to eliminate dead space” (p. 77). Dead space (e.g., tunnelling) in the wound is not filled with dressing and will allow wound debris to accumulate in that area, which may cause an abscess.

Do not pack the wound too tightly. Overpacking the wound causes pressure on the tissue in the wound bed, decreasing blood flow to the area and preventing healing and wound closure. Document the amount of packing placed in the wound to ensure there is no chance for any packing material to be left in the wound when the dressing is changed.

Securing Dressings. Use tape, ties, a secondary dressing, or gauze net to secure a dressing over a wound site. The choice of anchoring depends on the wound size and location, the presence of drainage, frequency of dressing changes, and patient’s level of activity. Of equal importance is the potential for skin stripping as tape is applied and removed frequently from the same area of skin. Patients with chronic wounds tend to have skin that is fragile and prone to breakdown. Thus, pay attention to the method used in affixing dressings.

If tape must be used, ensure that the periwound skin is not excoriated or at risk of breakdown. Make sure the patient does not have an allergy or sensitivity to tape. Nonallergenic paper and silicone tapes are available to minimize skin reactions. Common adhesive tape adheres strongly to the skin’s surface, whereas elastic adhesive tape compresses closely around pressure bandages and permits more movement of a body part. Skin sensitive to adhesive tape becomes severely inflamed and denuded and, in some cases, even sloughs when the tape is removed. Assess the skin under the tape at each dressing change. If the skin does not remain intact or is irritated, use an alternative solution (e.g., paper or silicone tapes or Montgomery ties).

Tape is available in various widths. Choose the size that sufficiently secures the dressing. Strips of 7.6 cm adhesive tape will likely ensure that a large dressing does not continually slip off. Other options, such as gauze wrap or burn-net dressings, may also be used.

When applying tape, ensure that the skin is dry so that the tape will adhere to several centimeters of skin on both sides of the dressing. Also place tape across the middle of the dressing. When securing the dressing, press the tape gently, exerting pressure away from the wound. With tension occurring in both directions away from the wound, skin distortion and irritation is minimized. Never apply tape over irritated or broken skin. Barrier film or spray can assist with adherence of the tape and protect the periwound skin from breakdown due to tape adhesives.

To remove tape safely, loosen the tape ends and gently pull the outer end parallel with the skin surface toward the wound. Apply light traction to the skin away from the wound as the tape is loosened and removed. The traction minimizes pulling of the skin. If tape covers an area of hair growth, the patient

Figure 46-23 Montgomery ties. **A**, Each tie is placed at side of dressing. **B**, Securing ties encloses dressing.

experiences less discomfort if you pull the tape in the direction of hair growth. Adhesive remover can also be used to release the tape from the skin, but can also dry out the skin.

When frequent dressing changes are required, particularly for large abdominal or chest wounds, avoid repeated removal of tape from sensitive skin by using dressings secured with pairs of reusable Montgomery ties (Figure 46-23). Each section consists of a long strip; half contains an adhesive backing to apply to the skin, and the other half folds back and contains a cloth tie to fasten across a dressing and untie at dressing changes.

Comfort Measures. A wound is often painful, depending on the extent of tissue injury and the patient's other medical health issues. Use several techniques to minimize discomfort during wound care. Administration of analgesic medications 30 to 45 minutes before dressing changes (depending on a drug's time of peak action) reduces discomfort. Careful removal of tape, gentle cleansing of wound edges, and careful manipulation of dressings and drains minimize stress on sensitive tissues. Often, propping and positioning the patient with pillows or foam wedges can decrease positioning pain or discomfort, particularly in complex, time-consuming dressing changes.

Surgical or Traumatic Wound Considerations

Basic Skin Cleansing for Surgical or Traumatic Wounds. Cleanse surgical or traumatic wounds by applying noncytotoxic solutions with sterile gauze or by irrigating. The following three principles are important when cleansing an incision or the area surrounding a drain:

1. Cleanse in a direction from the least contaminated area, such as from the wound or incision to the surrounding skin (Figure 46-24) or from an isolated drain site to the surrounding skin (Figure 46-25).

Figure 46-24 Methods for cleansing a wound site.

Figure 46-25 Cleansing a drain site.

2. Use gentle friction when applying solutions locally to the skin.
3. When irrigating, allow the solution to flow from the least to most contaminated area (see Skill 46-5).

Never use the same piece of gauze to cleanse across an incision or wound twice. Use gauze to clean the periwound skin, not the open wound. Open wound beds are damaged by the abrasive contact of gauze.

Cleansing Skin and Drain Sites. In cases in which the open drain leaks onto surrounding skin, ensure that the drainage is removed from the skin to avoid maceration or excoriation of the tissue from possibly caustic drainage. You may also need to clean the drain itself on a regular basis to avoid a buildup of potentially contaminated material.

Drain sites are a source of contamination because moist drainage harbours microorganisms. If a wound has a dry incisional area and a moist drain site, use two separate swabs or gauze pads, one to cleanse from the top of the incision toward the drain and one to cleanse from the bottom of the incision toward the drain. To cleanse the area of an isolated drain site, clean around the drain, moving in circular rotations outward from a point closest to the drain. In this situation, the skin near the site is more contaminated than the site itself. To cleanse circular wounds, use the same technique as in cleansing around a drain.

Irrigation. Irrigation is a special way of cleansing wounds. You use an irrigating syringe to flush the area with a constant low-pressure flow of noncytotoxic solution (usually saline). The gentle washing action of the irrigation cleanses a wound of exudate and debris. Irrigations are particularly useful for open, deep wounds. "*Irrigate, irrigate, irrigate . . . and then irrigate some more.*" However, make sure that the irrigant is not left pooled in the wound bed (usually by repositioning the patient to allow gravity to assist in drainage).

Wound Irrigation. Irrigation of an open wound requires sterile technique. Use a 35 mL syringe with a 19-gauge angiocatheter (Rolstad & Ovington, 2007) or a single-use bottle of normal saline to deliver the solution, so as not to damage healing wound tissue. Never occlude a wound opening with a syringe, because this results in the introduction of irrigating fluid into a closed space. In this case, the pressure of the fluid causes tissue damage and discomfort. Always irrigate a wound with the syringe tip over but not in the drainage site. Make sure fluid flows directly into the wound and not over a contaminated area before entering the wound. Skill 46-4 lists steps for wound irrigation.

Sutures. A surgeon closes a wound by bringing the wound edges as close together as possible to reduce scar formation. Proper wound closure involves control of bleeding and minimal trauma and tension to tissues.

Sutures are threads or metal used to sew body tissues together. The patient's history of wound healing, the site of surgery, the tissues involved, and the purpose of the sutures determine choice of suture material. For example, if the patient has had repeated surgery for an abdominal hernia, wire sutures may be used to provide greater strength for wound closure. In contrast, a small laceration of the face calls for use of very fine polyester sutures to minimize scar formation.

Sutures are available in a variety of materials, including silk, steel, cotton, linen, wire, nylon, and polyester. Steel staples are a common type of outer skin closure that cause less trauma to tissues than do sutures, while providing extra strength. Tape closures such as Steri-Strips applied over the wound to keep the edges closed are also common.

Sutures are placed within tissue layers in deep wounds as well as superficially, as the final means for wound closure. Deep sutures are usually an absorbable material that will disappear over time; however, sutures are foreign bodies and, thus, are capable of causing local inflammation. The surgeon tries to minimize tissue injury by using the finest suture possible and the smallest number necessary.

Suture Removal. Policies vary within institutions as to who is able to remove sutures. If it is appropriate for the nurse to remove them, an order is required. Special scissors with curved cutting tips or special staple removers slide under the skin closures for suture removal (Figure 46-26). If the suture line appears to be healing better in certain locations than in

others, the surgeon may choose to have only some sutures removed (e.g., every other one).

To remove staples, simply insert the tips of the staple remover under each wire staple. While slowly closing the ends of the staple remover together, you squeeze the centre of the staple with the tips, freeing the staple from the skin (see Figure 46-26).

To remove sutures, first check the type of suturing used (Figure 46-27). With intermittent suturing, the surgeon ties each individual suture made in the skin. Continuous suturing, as the name implies, is a series of sutures with only two knots, one at the beginning and one at the end of the suture line.

Figure 46-26 Staple remover.

Figure 46-27 Examples of suturing methods. A, Intermittent. B, Continuous. C, Blanket continuous. D, Retention.

► SKILL 46-4 Performing Wound Irrigation

video

Delegation Considerations

The skill of wound irrigation should not be delegated to unregulated care providers (UCPs). In the case of a chronic wound, you can delegate cleansing of the wound with clean technique to a UCP. Assessment of any wound, care of acute new wounds, and evaluation of wound irrigation is the responsibility of the nurse, however, and is never delegated. When a wound is stable or requires clean irrigation, instruct the UCP to do the following:

- Report any change in wound appearance or increased wound drainage to the nurse
- Use proper clean technique to avoid cross-contamination from irrigation syringes and equipment

Equipment

- Irrigant or cleansing solution (volume 1.2 to 2 times the estimated wound volume)
- Irrigation delivery system, depending on amount of pressure desired:
 - Sterile 35-mL irrigation syringe with sterile soft angiocatheter or 19-gauge needle (AHCPR, 1994) or
 - Whirlpool or hand-held shower
- Disposable gloves and sterile gloves (check agency policy)
- Waterproof underpad, if needed
- Dressing supplies
- Disposable waterproof bag
- Gown, if risk of spray
- Goggles, and/or mask if risk of spray

Continued

► SKILL 46-4 Performing Wound Irrigation—cont'd

Procedure

STEPS

1. Assess patient's level of pain. Administer prescribed analgesic 30 to 45 minutes before starting wound irrigation procedure.
2. Review medical record for physician's prescription for irrigation of open wound and type of solution to be used.
3. Assess recent recording of signs and symptoms related to patient's open wound.
 - A. Condition of skin and wound
 - B. Elevation of body temperature
 - C. Drainage from wound (amount, colour)
 - D. Odour
 - E. Consistency of drainage
4. Explain procedure of wound irrigation and cleansing.
5. Perform hand hygiene.
6. Position patient comfortably to permit gravitational flow of irrigating solution through wound and into collection receptacle. Position patient so that wound is vertical to collection basin.
7. Warm irrigation solution to approximate body temperature.
8. Form cuff on waterproof bag and place it near bed.
9. Close room door or bed curtains.
10. Apply gown, goggles, or mask, if needed.
11. Put on disposable gloves, remove soiled dressing, and discard in waterproof bag. Discard gloves.
12. Prepare equipment; open sterile supplies.
13. Put on sterile gloves (check agency policy).
14. Irrigate wound with wide opening:
 - A. Fill 35 mL syringe with irrigation solution.
 - B. Attach 19-gauge needle or angiocatheter.
 - C. Hold syringe tip 2.5 cm above upper end of wound and over area being cleansed.
 - D. Using continuous pressure, flush wound; repeat steps 14A, 14B, and 14C until solution draining into basin is clear.
15. Irrigate deep wound with very small opening:
 - A. Attach soft angiocatheter to filled irrigating syringe.
 - B. Lubricate tip of catheter with irrigating solution; then gently insert tip of catheter and pull out about 1 cm.
 - C. Using slow, continuous pressure, flush wound.
16. Cleanse wound with hand-held shower:
 - A. With patient seated comfortably in shower chair, adjust spray gentle flow; water temperature should be warm.

RATIONALE

- Discomfort may be related directly to the wound or indirectly to muscle tension or immobility. Increased comfort permits patient to move more easily and be positioned to facilitate wound irrigation.
- Open wound irrigation requires medical order, including type of solution to use.
- Data are used as baseline to indicate change in condition of wound (Sibbald, Orsted, et al., 2006).
- Elevated temperature may indicate response to infection.
- Amount will decrease as healing takes place.
- Strong odour may indicate infection.
- Leukocytes produce thick drainage.
- Information will reduce patient's anxiety.
- Transmission of microorganisms is reduced.
- Directing solution from top to bottom of wound and from clean to contaminated area prevents further infection. Positioning patient during planning stage provides bed surfaces for later preparation of equipment.
- Warmed solution increases comfort and reduces vascular constriction response in tissues.
- Cuffing helps to maintain large opening, thereby permitting placement of contaminated dressing without touching refuse bag itself.
- Privacy is maintained.
- Gown, goggles, and mask protect you from splashes or sprays of blood and body fluids.
- Transmission of microorganisms is reduced.
- Flushing wound helps remove debris and facilitates healing by secondary intention.
- Angiocatheter provides ideal pressure for cleansing and removal of debris.
- Holding the tip above the wound prevents syringe contamination. Careful placement of the syringe prevents unsafe pressure of the flowing solution.
- Clear solution indicates that all debris has been removed.
- Catheter permits direct flow of irrigant into wound. Expect wound to take longer to empty when opening is small.
- Tip is not in fragile inner wall of wound.
- Sterile solution will not be contaminated.
- Method is useful for patients able to shower with assistance or independently. Shower may be accomplished at home. A shower table is helpful for bed-bound or acutely ill patients.

Critical Decision Point: Caution: Splashing may occur during this step.

► SKILL 46-4 Performing Wound Irrigation—cont'd**video**

- B. Cover showerhead with clean washcloth, if needed.
- C. Shower for 5 to 10 minutes with showerhead 30 cm from wound.

Critical Decision Point: Consider culturing a wound if it has a foul and purulent odour, if inflammation surrounds the wound, if a nondraining wound begins to drain, or if the patient is febrile.

17. Obtain cultures, if needed, after cleansing with nonbacteriostatic saline.
 18. Dry wound edges with gauze; dry patient, if shower or whirlpool is used.
 19. Apply appropriate dressing (see Skill 46-3 and Box 46-13).
 20. Remove gloves and, if worn, mask, goggles, and gown.
 21. Dispose of equipment and soiled supplies. Perform hand hygiene.
 22. Assist patient to comfortable position.
 23. Assess type of tissue in the wound bed.
 24. Inspect dressing periodically.
 25. Evaluate skin integrity.
 26. Observe patient for signs of discomfort.
 27. Observe for presence of retained irrigant.
- Routine culturing of open wounds is not recommended in the AHCPR guidelines (1994). If required, quantitative bacterial cultures (tissue biopsy or wound fluid by needle aspiration) should be performed rather than swab cultures, which often detect only surface bacterial contaminants.
 - Maceration of surrounding tissue is prevented if excess moisture is dried.
 - Protective barrier and healing environment for wound is maintained.
 - Transfer of microorganisms is prevented.
 - Transmission of microorganisms is reduced.
 - Wound healing progress is identified and type of wound cleansing needed is determined.
 - Patient's response to wound irrigation and need to modify plan of care are determined.
 - Whether extension of wound has occurred is determined.
 - Patient's pain should not increase as a result of wound irrigation.
 - Retained irrigant is a medium for bacterial growth, and subsequent infection may occur.

Unexpected Outcomes

Wound does not appear to heal

Wound drainage increases

Related Interventions

- Obtain wound culture.
- Notify physician, who may change frequency of dressing, irrigation, or both.
- Apply more absorbent gauze.
- Increase the frequency of irrigation.

Recording and Reporting

- Record wound irrigation and patient response on progress notes.
- Immediately report to attending physician any evidence of fresh bleeding, sharp increase in pain, retention of irrigant, or signs of shock.
- At change of shift, report expected and unexpected outcomes that have occurred.

Home Care Considerations

- Teach patient and caregiver how to make normal saline, especially if cost is an issue. Normal saline can be made by using 10 mL of salt in 1 L of boiling water (Barr, 1995).
- Tell patient and caregiver that because normal saline has no preservatives, it should be discarded 24 to 48 hours after it is first opened or made (Barr, 1995).

Retention sutures are placed more deeply than skin sutures, and nurses may or may not remove them, depending on agency policy.

The manner in which the suture crosses and penetrates the skin determines the method for removal. Never pull the visible portion of a suture through underlying tissue. Sutures on the skin's surface harbour microorganisms and debris, but the portion of the suture beneath the skin is sterile. Pulling the contaminated portion of the suture through tissues may lead to infection. Clip suture materials as close to the skin edge on one side as possible and pull the suture through from the other side (Figure 46-28).

Drainage Evacuation. When drainage interferes with healing, you achieve drainage evacuation by using either a

Figure 46-28 Removal of intermittent suture. **A**, Cut the suture as close to the skin as possible, away from the knot. **B**, Remove the suture and never pull the contaminated stitch through the tissues.

Figure 46-29 Setting the suction on a drainage evacuator. 1. With the drainage port open, the lever on the diaphragm is raised. 2. Push straight down on the lever to lower the diaphragm. 3. Closure of the port prevents escape of air and creates vacuum pressure.

drain alone or a drainage tube with continuous suction. Apply special skin barriers, including hydrocolloid dressings, similar to those used with ostomies (see Chapter 44), around drain sites. The skin barriers are soft material applied to the skin with adhesive. Drainage flows on the barrier but not directly on the skin.

Drainage evacuators (Figure 46-29) are convenient, portable units that connect to tubular drains lying within a wound bed and exert a safe, constant, low-pressure vacuum to remove and collect drainage. Ensure suction is exerted and connection points between the evacuator and tubing are intact. After the evacuator collects drainage, assess for volume and character every shift and as needed. When the evacuator fills, measure output by emptying the contents into a graduated cylinder and immediately reset the evacuator to apply suction.

Bandages and Binders. A simple gauze dressing is often not enough to immobilize or provide support to a wound. Binders and bandages applied over or around dressings provide extra protection and therapeutic benefits by doing the following:

- Creating pressure over a body part (e.g., an elastic pressure bandage applied over an arterial puncture site)
- Immobilizing a body part (e.g., an elastic bandage applied around a sprained ankle)
- Supporting a wound (e.g., an abdominal binder applied over a large abdominal incision and dressing)
- Reducing or preventing edema (e.g., a well-supporting bra to minimize breast discomfort after delivery of a baby)
- Securing a splint (e.g., a bandage applied around hand splints for correction of deformities)
- Securing dressings (e.g., elastic webbing applied around leg dressings after a vein stripping)

Bandages are available in rolls of various widths and materials, including gauze, elasticized knit, elastic webbing, flannel, and muslin. Gauze bandages are lightweight and inexpensive, conform easily to the contours of the body, and permit air circulation to prevent skin maceration. Elastic bandages conform well to body parts but also exert pressure.

Principles for Applying Bandages and Binders. Correctly applied bandages and binders do not cause injury to underlying and nearby body parts or create discomfort for the patient. For example, a chest binder should not be so tight as to restrict

chest wall expansion. Before applying a bandage or binder, the following are your responsibilities:

- Inspecting the skin for abrasions, edema, discolouration, or exposed wound edges
- Covering exposed wounds or open abrasions with a sterile dressing
- Assessing the condition of underlying dressings and changing them, if soiled
- Assessing the skin of underlying areas that will be distal to the bandage for signs of circulatory impairment (coolness, pallor or cyanosis, diminished or absent pulses, swelling, numbness, and tingling) to provide a means for comparing changes in circulation after bandage application

After applying a bandage, you need to assess, document, and immediately report changes in circulation, skin integrity, comfort level, and body function (e.g., ventilation, movement). When you apply the bandage, readjust it, as necessary. Make sure you explain to the patient that the binder may feel relatively firm or tight. Carefully assess a bandage to be sure that it is properly applied (according to the written order) and is providing therapeutic benefit. Replace any soiled bandages.

Binder Application. Binders are especially designed for the body part to be supported. Most binders are made of elastic or cotton. The most common types of binders are the abdominal binder and breast binder (Skill 46-5). Well-fitting bras are now replacing breast binders. Both provide support after breast surgery or exert pressure to reduce lactation in a woman after childbirth.

Abdominal Binders. An abdominal binder supports large abdominal incisions that are vulnerable to tension or stress as the patient moves or coughs. Secure an abdominal binder with safety pins, Velcro strips, or metal stays.

Bandage Application. Rolls of bandage secure or support dressings over irregularly shaped body parts. Each roll has a free outer end and a terminal end at the centre of the roll. The rolled portion of the bandage is its body, and its outer surface is placed against the patient's skin or dressing. Skill 46-6 describes the steps for applying an elastic bandage.

The Whole Person, the Whole Team

Skin management and wound care require the involvement of the health care team because the factors that create skin breakdown, such as pressure and nutrition, are assessed and treated by experts within the health care team: physiotherapist, occupational therapist, dietitian, nurse, physician, social worker, and pharmacist. In addition, the wound belongs to the patient and you need to recognize the impact of the individual on both the development and healing potential of a wound.

Case Study. Mr. John Purata is an 84-year-old man who has returned to his home in a long-term care facility where you are looking after the ulcer on his sacrum, developed during his stay in acute care after hip replacement surgery. Mr. Purata has been too tired to get up for meals, and you have noticed that his nutritional status is declining. Although he is on a pressure-relief surface, Mr. Purata tends to lie on his back. You have mentioned to him the importance of repositioning to assist in healing the wound, but he merely closes his eyes and tells you he is fine the way he is. When you and the other staff in the long-term care facility try to get him up to walk, Mr. Purata is hesitant and requires a great deal of coaching and encouragement to walk even a few steps. He then says he is too tired to

SKILL 46-5 Applying an Abdominal or Breast Binder**Delegation Considerations**

The skills of applying a binder (abdominal or breast) can be delegated to unregulated care providers (UCPs). You are responsible for wound assessment and the evaluation of wound care interventions. Also complete an assessment of the patient's ability to breathe deeply, cough effectively, and move independently; assess skin for irritation or abrasion; assess the incision or wound and dressing; and assess the patient's comfort level before a binder or sling is applied for the first time. When delegating the skill of applying a binder, instruct the UCP to do the following:

- Immediately report any change in the patient's respiratory status
- Report an increase in wound drainage
- Report changes in skin integrity under or adjacent to the binder
- Remove the binder at prescribed intervals

Equipment

- Disposable gloves, if wound drainage is present
- Abdominal binder:
- Correct size cloth or elastic straight binder
- Safety pins (6 to 8), unless Velcro closure or metal fasteners are attached
- Breast binder:
- Correct size binder
- Safety pins (approximately 12), unless Velcro closure is attached

Procedure**STEPS**

1. Observe patient with need for support of thorax or abdomen. Observe ability to breathe deeply and cough effectively.
2. Review medical record, if medical prescription for particular binder is required, and reasons for application.
3. Inspect skin for actual or potential alterations in integrity. Observe for irritation, abrasion, skin surfaces that rub against each other, or allergic response to adhesive tape used to secure dressing.
4. Inspect any surgical dressing.

RATIONALE

- Baseline assessment determines patient's ability to breathe and cough. Impaired ventilation of lungs can lead to alveolar atelectasis and inadequate arterial oxygenation.
- Application of supportive binders may be used on nursing judgement. In some situations, physician input is required.
- Actual impairments in skin integrity can be worsened with application of a binder. Binder can cause pressure and excoriation.
- Dressing replacement or reinforcement precedes application of any binder.

Critical Decision Point: Dressing should be clean and dry, and incision or wound should be entirely covered by dressing.

5. Assess patient's comfort level, using analogue scale of 0 to 10 (see Chapter 41), noting any objective signs and symptoms of pain.

- Data will determine effectiveness of binder placement.

Critical Decision Point: Expect patient in moderate to severe pain to have diaphoresis, tachycardia, and elevated blood pressure.

6. Gather necessary data regarding size of patient and appropriate binder.
7. Explain procedure to patient.
8. Teach skill to patient or significant other.
9. Perform hand hygiene and apply gloves (if likely to contact wound drainage).
10. Close curtains or room door.
11. Apply binder.
 - A. Abdominal binder:
 - (1) Position patient in supine position with head slightly elevated and knees slightly flexed.
 - (2) Fanfold far side of binder toward midline of binder.
 - (3) Instruct and help patient to roll away from you toward raised side rail while firmly supporting abdominal incision and dressing with hands.
 - (4) Place fanfolded ends of binder under patient.
 - (5) Instruct or assist patient to roll over folded ends.
 - (6) Unfold and stretch ends out smoothly on far side of bed.
 - (7) Instruct patient to roll back into supine position.
 - (8) Adjust binder so that supine patient is centred over binder using symphysis pubis and costal margins as lower and upper landmarks.

- Proper fit of binder will be ensured.
- Patient will understand and be more cooperative.
- Anxiety is reduced and continuity of care after discharge is ensured.
- Transmission of microorganisms is reduced.
- Patient's comfort and dignity are maintained.
- Muscular tension on abdominal organs is minimized.
- Patient's time in uncomfortable position is reduced.
- Pain and discomfort is reduced.
- Placement and centring of binder is accomplished with minimal discomfort.
- Skin integrity and comfort is maintained.
- Chest expansion and adequate wound support is facilitated when binder is closed.
- Support from binder is centred over abdominal structures, which reduces incidence of decreased lung expansion.

Critical Decision Point: Cover any exposed areas of an incision or wound with sterile dressing.

► SKILL 46-5 Applying an Abdominal or Breast Binder—cont'd

- (9) Close binder. Pull one end of binder over centre of patient's abdomen. While maintaining tension on that end of binder, pull opposite end of binder over centre and secure with Velcro closure tabs, metal fasteners, or horizontally placed safety pins.

B. Breast binder:

- (1) Assist patient in placing arms through binder's armholes.
 - (2) Assist patient to supine position in bed.
 - (3) Pad area under breasts, if necessary.
 - (4) Using Velcro closure tabs or horizontally placed safety pins, secure binder at nipple level first. Continue closure process above and then below nipple line until entire binder is closed.
 - (5) Make appropriate adjustments, including individualizing fit of shoulder straps and pinning waistline darts to reduce binder size.
 - (6) Instruct and observe skill development in self-care related to reapplying breast binder.
12. Remove gloves and perform hand hygiene.
 13. Assess patient's comfort level, using analogue scale of 0 to 10, noting any objective signs and symptoms.
 14. Adjust binder, as necessary.
 15. Observe site for skin integrity, circulation, and characteristics of the wound. (Periodically remove binder and surgical dressing to assess wound characteristics.)
 16. Assess patient's ability to breathe properly.
 17. Identify patient's need for assistance with activities such as combing hair.

- Continuous wound support and comfort is provided.
- Binder placement process is made easier for patient.
- Supine positioning facilitates normal anatomical position of breasts; facilitates healing and comfort.
- Skin contact with undersurface is prevented.
- Horizontal placement of pins may reduce risk of uneven pressure or localized irritation.
- Support to patient's breasts is maintained.
- Self-care is an integral aspect of discharge planning. Skin integrity and comfort level goals are ensured.
- Cross-infections are prevented.
- Effectiveness of binder placement is determined. Binders should not increase discomfort.
- Comfort and chest expansion is promoted.
- Binder should not result in complication to skin, wound, or underlying organs.
- Any impaired ventilation and potential pulmonary complications are identified.
- Mobility of upper extremities may be limited, depending on severity and location of incision.

Unexpected Outcomes*Patient's pain increases**Patient develops impaired skin integrity under the binder***Related Interventions**

- Remove binder and assess wound.
- Reapply binder using less pressure.
- Remove binder.
- Initiate skin care measure to heal affected site.

Recording and Reporting

- Report any skin irritation at between-shift report.
- Record application of binder, condition of skin, circulation, integrity of dressing, and patient's comfort level.
- Report ineffective lung expansion to physician immediately.

Home Care Considerations

- Abdominal and breast binders can be washed and hung to dry.
- Instruct caregiver to avoid excessive pressure with binder application.

► SKILL 46-6 Applying an Elastic Bandage**Delegation Considerations**

The application of an elastic bandage can be delegated to UCPs. You are responsible for wound assessment and the evaluation of the wound. In addition, you should assess for adequate circulation to the extremity distal to the elastic bandage (e.g., pulse, skin temperature, capillary refill). When delegating this skill to a UCP, instruct about any restrictions that the patient might have (e.g., unable to independently raise leg or independently roll over). Also instruct the UCP to report the following:

- Any change in the skin colour of the patient's injured extremity
- Any increases in the patient's pain

Equipment

- Correct width and number of bandages
- Safety pins, clips, or adhesive tape
- Disposable gloves, if wound drainage is present

► SKILL 46-6 Applying an Elastic Bandage—cont'd

Procedure

STEPS

1. Perform hand hygiene and apply gloves, if needed. Inspect skin for alterations in integrity as indicated by abrasions, discolouration, chafing, or edema. (Look carefully at bony prominences.)
2. Inspect surgical dressing. Remove gloves and perform hand hygiene.
3. Observe adequacy of circulation (distal to bandage) by noting surface temperature, skin colour, and sensation of body parts to be wrapped.
4. Review medical record for specific orders related to application of elastic bandage. Note area to be covered, type of bandage required, frequency of change, and previous response to treatment.
5. Identify patient's and primary caregiver's present knowledge level of skill, if bandaging will be continued at home.
6. Explain procedure to patient.
7. Teach skill to patient or primary caregiver.
8. Perform hand hygiene and apply gloves if drainage is present.
9. Close room door or curtains.
10. Help patient to assume comfortable, anatomically correct position.

RATIONALE

- Altered skin integrity contraindicates the use of elastic bandages.
- Surgical dressing replacement or reinforcement precedes application.
- Comparison of area before and after application of bandage is necessary to ensure continued adequate circulation. Impairment of circulation may result in coolness to touch when compared with opposite side of body, cyanosis or pallor of skin, diminished or absent pulses, edema or localized pooling, and numbness or tingling of part.
- Specific prescription may direct procedure, including factors such as extent of application (e.g., toe to knee, toe to groin) and duration of treatment.
- Planning and teaching should be individualized.
- Increased knowledge promotes cooperation and reduces anxiety.
- Anxiety is reduced and continuity of care after discharge is ensured.
- Transmission of microorganisms is reduced.
- Patient's comfort and dignity are maintained.
- Alignment is maintained, and musculoskeletal deformity is prevented.

Critical Decision Point: Bandages applied to lower extremities are applied before patient sits or stands. Elevation of dependent extremities for 20 minutes before bandage application will enhance venous return.

11. Hold roll of elastic bandage in dominant hand and use other hand to lightly hold beginning of bandage at distal body part. Continue transferring roll to dominant hand as bandage is wrapped.

- Appropriate and consistent bandage tension is maintained.

Critical Decision Point: Toes or fingertips should be visible for follow-up circulatory assessment.

12. Apply bandage from distal point toward proximal boundary using variety of turns to cover various shapes of body parts.
13. Unroll and very slightly stretch bandage.
14. Overlap turns by one-half to two-thirds width of bandage roll.
15. Secure first bandage with clip or tape before applying additional rolls.
16. Apply additional rolls without leaving any uncovered skin surface. Secure last bandage applied.
17. Remove gloves, if worn, and perform hand hygiene.
 - A. Assess distal circulation when bandage application is complete and at least twice during eight-hour period.
 - B. Observe skin colour for pallor or cyanosis.
 - C. Palpate skin for warmth.
 - D. Palpate pulses and compare bilaterally.
 - E. Ask if patient is aware of pain, numbness, tingling, or other discomfort.
 - F. Observe mobility of extremity.
18. Have patient demonstrate bandage application.

- Bandage is applied in a manner that conforms evenly to body part and promotes venous return.
- Uniform bandage tension is maintained.
- Uneven bandage tension and circulatory impairment is prevented.
- Wrinkling and loose ends are prevented.
- Transmission of microorganisms is reduced.
- Early detection and management of circulatory impairment ensures healthy neurovascular status.
- Neurovascular changes indicate impaired venous return.
- Joint immobility is determined; if bandage is too tight, movement will be restricted.
- Return demonstration documents learning.

Continued

► SKILL 46-6 Applying an Elastic Bandage—cont'd

Unexpected Outcomes

Impaired circulation distal to elastic bandage

Break in skin under elastic bandage

Inability of patient to change dressing

Related Interventions

- Release bandage.
- Palpate extremity and assess pulse, temperature, and capillary refill.
- Reapply dressing with less pressure.
- Remove bandage.
- Reapply bandage with less pressure.
- Determine barriers to applying bandage.
- Explore options (e.g., different type of dressing).

Recording and Reporting

- Document condition of the wound, integrity of dressing, application of bandage, circulation, and patient's comfort level.
- Report any changes in neurological or circulatory status to the nurse in charge or physician.

Home Care Considerations

- Instruct patient or caregiver not to secure bandages too tightly, which interferes with circulation.
- Elastic bandages that are used to reduce swelling are best applied to the feet in the morning, before getting out of bed.
- Always remove an elastic bandage daily and inspect the area.

go further and asks to go back to bed. He is frequently lying in bed, with eyes closed and the lights dim. His daughter and son are concerned that he seems to have lost his "get up and go" attitude. The wound is not improving, and you are concerned.

- What are the key issues that need to be addressed?
- What members of the health care team need to be involved?
- What would be realistic goals for Mr. Purata?
- How would you develop a plan of care for this patient?

❖ Evaluation

You evaluate nursing interventions for reducing and treating pressure ulcers by determining the patient's response to nursing therapies and whether the patient achieved each goal (Figure 46-30). To evaluate outcomes and responses to care, you measure the effectiveness of interventions. The optimal outcomes are to prevent injury to the skin and tissues, reduce injury to the skin and underlying tissues, and restore skin integrity.

Because each patient has different risk factors for impaired skin integrity, you need to individualize nursing interventions. Patients with minimal mobility impairments or relatively stable health status need only a few measures.

Patients with impaired skin integrity need assessment on an ongoing basis for factors that contribute to skin breakdown. This includes a comprehensive skin assessment and a wound assessment using a validated risk assessment tool. Assessment provides the foundation for the plan of care and is critical for monitoring the effectiveness of the plan (Nix, 2007).

Include the patient and the caregiver in the assessment process. Determine what they know about impaired skin integrity, and develop a plan of care to provide education. Chronic wounds such as pressure ulcers take time to heal, and it is likely that the patient will be in the home or long-term care setting with the pressure ulcer.

If the identified outcomes are not met for a patient with impaired skin integrity, questions to ask include the following:

Figure 46-30 Critical thinking model for skin integrity and wound care evaluation.

- Was the etiology of the skin impairment addressed? Were the pressure, friction, shear, and moisture components identified, and did the plan of care decrease the contribution of each of these components?
- Was wound healing supported by providing the wound base with a moist protected environment?

- Were issues such as nutrition assessed and a plan of care developed that provided the patient with the calories to support healing?

Finally, evaluate the need for additional referrals to other experts in wound management, such as occupational therapists, dietitians, and wound care specialists. Care of the patient with a pressure ulcer requires a multidisciplinary team approach.

✦ KEY CONCEPTS

- Prevention of skin breakdown is a major nursing focus for all patients, irrespective of their age or the health care setting.
- Patients should be assessed for risk of skin breakdown with the use of a validated risk assessment tool, such as the Braden Risk Assessment Tool, on admission to care and subsequently at least once per week.
- Alterations in mobility, sensory perception, level of consciousness, and nutrition, as well as the presence of moisture, increase the risk of pressure ulcer development.
- Preventive skin care is aimed at controlling external pressure on bony prominences and keeping the skin clean, well lubricated, hydrated, and free of excess moisture.
- Proper positioning (the 30-degree rule) reduces the effects of pressure and guards against shearing force.
- Wound assessment requires a description of the appearance of the wound base, size (length × width × depth), presence of exudate, and the periwound skin condition.
- Moist wound-healing approaches are based on evidence and support the healing cycle of wounds.
- Wounds require pressure off-loading, adequate nutrition and hydration, blood flow, and an absence of infection to heal.
- Arterial, venous, and diabetic wounds are often the result of impaired peripheral circulation to the extremities.
- Wound irrigation should be at room or body temperature and provide 4 to 15 psi of pressure to avoid damaging fragile granulating tissue.
- Therapeutic beds and mattresses redistribute the effects of pressure; however, base selection on assessment data to identify the best bed for individual needs.
- Cleansing and topical agents used to treat pressure ulcers vary according to the stage of the pressure ulcer and condition of the wound bed. Assessment of the ulcer will enable you to select proper skin care agents.
- Direct nutritional interventions at improving wound healing through increasing protein and calorie levels, as required.
- When extensive tissue loss occurs, a wound heals by secondary intention.
- The chances of wound infection are greater when the wound contains dead or necrotic tissue, when foreign bodies lie on or near the wound, and when the blood supply and tissue defences are reduced.
- The principles of wound first aid include control of bleeding, cleansing, and protection.
- The layers of a dry dressing absorb drainage and prevent the entrance of bacteria.
- A moist environment supports wound healing.
- When cleansing wounds or drain sites, clean from the least to most contaminated area, away from wound edges.
- Apply a bandage or binder in a manner that does not impair circulation or irritate the skin.

✦ CRITICAL THINKING EXERCISES

Mrs. Stein, who is 76 years of age, is at postoperative day 7 after a total hip replacement. She developed redness and oozing of foul-smelling, tan-coloured drainage from the hip incision on postoperative day 4. Significant medical history includes arthritis and mild hypertension. Because of surgical pain at the incision site, she did not easily transfer from her bed to the chair. Now on day 7, she notes some pain at the incision and complains of a painful, burning sensation in the sacral region. She is continent of urine and stool but continues to “scoot” over to the side of the bed when preparing for bed-to-chair transfers.

1. The staples from the surgical incision were removed and an order was written for a moist saline gauze dressing to be applied to the area three times a day. Would this be the approach that best supports wound healing? Provide a rationale and suggest alternative approaches. When the dressing is removed, what are the critical factors to assess?
2. A head-to-toe skin assessment is done per institutional policy on a daily basis. At the most recent assessment, redness was noted over the sacral area, and on direct examination, a small area of denuded tissue was noted. The involved area has minimal depth and a red, moist base. How would you describe the impairment in skin integrity in your charting?
3. What will you include in your plan of care to address the impairment in skin integrity in the sacral area?
4. Mrs. Stein will be discharged tomorrow. What issues must be assessed regarding her care before discharge? Explain why those issues are of importance.

✦ REVIEW QUESTIONS

1. When repositioning an immobile patient, you notice redness over a bony prominence. When the area is assessed, the red spot blanches with a fingertip touch, indicating
 1. A local skin infection requiring antibiotics
 2. This patient has sensitive skin and requires special bed linen
 3. A stage III pressure ulcer needing the appropriate dressing
 4. Reactive hyperemia, a reaction that causes the blood vessels to dilate in the injured area
2. This type of pressure ulcer is an observable, pressure-related alteration of intact skin, whose indicators, compared with an adjacent or opposite area on the body, may include changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or beefy feel), and sensation (pain or itching).
 1. Stage I
 2. Stage II
 3. Stage III
 4. Stage IV
3. When obtaining a wound culture to determine the presence of a wound infection, the specimen should be taken from the
 1. Necrotic tissue
 2. Wound drainage
 3. Drainage on the dressing
 4. Wound after it has first been cleansed with normal saline

4. Postoperatively, the patient with a closed abdominal wound reports a sudden "pop" after coughing. When you examine the surgical wound site, the sutures are open and pieces of small bowel are noted at the bottom of the now opened wound. The correct intervention would be to
 1. Allow the area to be exposed to air until all drainage has stopped
 2. Place several cold packs over the areas, protecting the skin around the wound
 3. Cover the areas with sterile saline-soaked towels and immediately notify the surgical team; this is likely to indicate a wound evisceration
 4. Cover the area with sterile gauze, place a tight binder over the areas, and ask the patient to remain in bed for 30 minutes because this is a minor opening in the surgical wound and should reseal quickly
5. Serous drainage from a wound is defined as
 1. Fresh bleeding
 2. Thick and yellow
 3. Clear, watery plasma
 4. Beige to brown and foul-smelling
6. Before changing a dressing, you should
 1. Read the medical orders and follow them exactly
 2. Gather together all the supplies that might be required for the dressing change and remove the dressing from the wound
 3. Discuss the plan to change the dressing with the patient, assess the need for analgesia, and provide it, if necessary
 4. Tell the family to leave the room because dressings can be difficult for non-health care providers to see
7. Interventions to manage a patient who is experiencing fecal and urinary incontinence include
 1. Keeping the buttocks exposed to air at all times
 2. Use of large absorbent diapers that are changed when saturated
 3. Utilization of an incontinence cleanser, followed by application of a moisture barrier ointment
 4. Frequent cleansing, application of an ointment, and coverage of the areas with a thick, absorbent towel
8. The best description of a hydrocolloid dressing is
 1. A seaweed derivative that is highly absorptive
 2. Premoistened gauze placed over a granulating wound
 3. A debriding enzyme that is used to remove necrotic tissue
 4. A dressing that forms a gel that interacts with the wound surface
9. A binder placed around a surgical patient with a new abdominal wound is indicated for
 1. Collection of wound drainage
 2. Reduction of abdominal swelling
 3. Reduction of stress on the abdominal incision
 4. Stimulation of peristalsis (return of bowel function) by direct pressure
10. Patients with pressure ulcers require
 1. Repositioning every four to six hours
 2. Bed rest and a quiet environment
 3. Frequent dressing changes
 4. Nutritional assessment from a dietitian

✦ RECOMMENDED WEB SITES

Canadian Association for Enterostomal Therapy (CAET): <http://www.caet.ca>

CAET is an association of health care providers (ET nurses) promoting education, research, and standards for enterostomal nursing practice. Nurses with the ET designation have obtained additional post-baccalaureate level certification to offer care to patients with the following conditions: abdominal stomata (openings), fistulae, draining wounds, and selected disorders of the integumentary (skin), gastrointestinal, and genitourinary systems.

Canadian Association of Wound Care (CAWC): <http://cawc.net>

The CAWC is an interprofessional national organization dedicated to prevention, treatment, evaluation, and scholarship regarding wound care across the continuum of care. The CAWC Web site has quick reference guides and best practice articles available for downloading on all aspects of wound care practice, as well as information on upcoming seminars, conferences, and scholarship funding opportunities.

European Pressure Ulcer Advisory Panel: <http://www.epuap.org>

Created in 1996, this group of health care providers and wound care experts works to lead and support all European countries in the efforts to prevent and treat pressure ulcers. The mission statement is "to provide the relief of persons suffering from or at risk of pressure ulcers, in particular through research and the education of the public." Numerous links to European wound care organizations appear on the Web site.

National Pressure Ulcer Advisory Panel (NPUAP): <http://www.npuap.org>

The NPUAP provides multidisciplinary leadership for improved patient outcomes in pressure ulcer prevention and management through education, public policy, and research.

Registered Nurses' Association of Ontario (RNAO) Best Practice Guidelines: <http://www.rnao.org/bestpractices>

This Web site provides links to the RNAO Best Practice Guidelines, including Risk Assessment and Prevention of Pressure Ulcers and Assessment and Management of Stage I to IV Pressure Ulcers, which can be downloaded as a pdf file or purchased through RNAO.

Wound, Ostomy, and Continence Nurses (WOCN) Society: <http://www.wocn.org>

The WOCN Society is a professional nursing society that supports the practice and delivery of expert health care to patients with wounds, ostomies, and incontinence.

World Wide Wounds: <http://www.worldwidewounds.com>

World Wide Wounds is an online, peer-reviewed journal with a focus on current research and evidence-informed practice issues.

Wound Care Management: <http://www.lhsc.on.ca/wound>

This Web site is a clinical resource, based on evidence-informed best practices for wound care. The site includes numerous links to online resources, and typical wounds and dressing options.

Sensory Alterations

Original chapter by Jill Parsons, RN, MSN, PCCN

Canadian content written by Pamela G. Hawranik, RN, MN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Differentiate among the processes of reception, perception, and reaction to sensory stimuli.
- Discuss the relationship of sensory function to an individual's level of wellness.
- Discuss common causes and effects of sensory alterations.
- Discuss common sensory changes that occur with aging.
- Identify factors important in the assessment of a patient's sensory status.
- Identify nursing diagnoses relevant to patients with sensory alterations.
- Develop a plan of care for patients with sensory deficits.
- List interventions for preventing sensory deprivation and controlling sensory overload.
- Describe conditions in the health care agency or patient's home that you can adjust to promote meaningful sensory stimulation.
- Discuss ways to maintain a safe environment for patients with sensory deficits.

People rely on a variety of sensory stimuli to give meaning and order to events occurring in their environment. The senses help form the perceptual base of our world (Touhy et al., 2012). Stimulation comes from many sources inside and outside the body, particularly through the senses of sight (**visual**), hearing (**auditory**), touch (**tactile**), smell (**olfactory**), and taste (**gustatory**). The body also has a **kinesthetic** sense that enables a person to be aware of the position and movement of body parts without seeing them. **Stereognosis** is a sense that allows a person to recognize an object's size, shape, and texture. Meaningful stimuli allow a person to learn about the environment and are necessary for healthy functioning and normal development.

The chapter author gratefully acknowledges Heather Cathro, RN, MN, for her assistance.

When sensory function is altered, the person's ability to relate to and function within his or her environment changes drastically. Sensory alterations can affect the individual's ability to manage care for themselves in their homes, decrease independence, and affect their ability to learn and adopt necessary self-care practices (Speros, 2009). Visual and hearing loss may affect communication, cognition, and mobility. Olfactory, tactile, and gustatory impairments may result in nutritional problems with resultant weight loss, dehydration, and skin breakdown. Many patients seeking health care have preexisting sensory alterations (e.g., cataracts). Others may develop sensory alterations as a result of medical treatment (e.g., hearing loss from antibiotic use). The health care environment itself can cause sensory alterations. For example, a hospital unit is often a place of unfamiliar sights, sounds, and smells, as well as a place that minimizes contact with family and friends. As a nurse, you must understand and help meet the needs of patients with sensory alterations, as well as recognize patients most at risk for developing sensory problems.

Scientific Knowledge Base

Normal Sensation

The nervous system continuously receives thousands of bits of information from sensory nerve receptors, relays the information through appropriate channels, and integrates the information into a meaningful response. Sensory stimuli reach the sensory receptors and can elicit an immediate reaction or present information to the brain to be stored for future use. The nervous system must be intact for sensory stimuli to reach appropriate brain centres and for the individual to perceive the sensation. After interpreting the significance of a sensation, the person can then react to the stimulus (Table 47-1).

Reception, perception, and reaction are the three components of any sensory experience. Reception begins with stimulation of a nerve cell called a receptor, which is usually designed for only one type of stimulus, such as light, touch, or sound. In the case of special senses, the receptors are grouped close together or located in specialized organs (McCance & Huether,

► TABLE 47-1 Normal Hearing and Vision

Function

The Ear

Transmits to the brain an accurate pattern of all sounds received from the environment, the relative intensity of these sounds, and the direction from which they originate.

External Ear

The purpose of the hair follicles and the cerumen is to protect against the entry of foreign matter into the canal and lubricate the canal to inhibit growth of bacteria and fungi. The external auditory canal shelters the tympanic membrane and maintains the elasticity of the tympanic membrane by maintaining a relatively constant temperature and humidity.

Middle Ear

The function of the middle ear is to transmit sound from the external auditory canal to the inner ear. The functions of the tympanic membrane are to cause the ossicles to vibrate in order to transmit sound waves to the inner ear and to protect the middle ear.

Inner Ear

When vibrations at the oval window are transmitted to the inner ear they distort and move the fluid and hair cells in the labyrinth. The inner ear converts sound waves for the transmission and interpretation by the brain regarding body position, sound, and movement. The impulses are then transmitted along the eighth cranial nerve to the brain.

The Eye

Transmits to the brain an accurate pattern of light reflected from solid objects in the environment and transformed into colour and hue.

Anatomy and Physiology

The auditory system is composed of three major parts: external ear, middle ear, and inner ear.

The external ear is composed of the auricle (or pinnae) and the external auditory canal. The pinnae direct and funnel sound waves into the external auditory canal and then to the eardrum (**tympanic membrane**). The outer one-third of the canal is lined with hair follicles and glands that secrete **cerumen** or ear wax.

The middle ear consists of the tympanic membrane, the ossicles, and the oval window. The tympanic membrane is located at an oblique angle at the end of the auditory canal.

The ossicles are three small bones (malleus, incus, and stapes). They are often nicknamed hammer, anvil, and stirrup, respectively.

Movement of the stapes in the oval window creates vibrations in the fluid of the inner ear.

The inner ear contains three interconnected bony structures: cochlea, vestibule, and semicircular canals. They are often called the labyrinth because of their winding canal system. They contain fluid and tiny hair cells.

The external parts of the eye include the eyebrows, eyelids, eyelashes, conjunctiva, cornea, sclera, and tear ducts. The internal structures include the sclera, cornea, choroid, ciliary body, iris, pupil, lens, and retina.

Light rays enter the convex cornea and begin to converge. Fine adjustment of light rays occurs as they pass through the pupil and through the lens. The ciliary muscles change the shape of the lens to focus the light on the retina.

The retina has a pigmented layer of cells to enhance visual acuity. The sensory retina contains the rods and cones—photoreceptor cells sensitive to stimulation from light.

Photoreceptor cells send electrical impulses by way of the optic nerve to the brain.

2006), such as the taste buds of the tongue or the retina of the eye. When a nerve impulse is created, it travels along pathways to the spinal cord or directly to the brain. For example, sound waves stimulate hair cell receptors within the organ of Corti (located in the inner ear), which causes impulses to travel along the eighth cranial nerve to the acoustic area of the temporal lobe. Sensory nerve pathways usually cross over to send stimuli to opposite sides of the brain. The actual perception or awareness of unique sensations depends on the receiving region of the cerebral cortex, where specialized brain cells interpret the quality and nature of sensory stimuli. When the person becomes conscious of the stimuli and receives the information, perception takes place. Perception includes integration and interpretation of the stimuli on the basis of the person's experiences. A person's level of consciousness influences how well stimuli are perceived and interpreted. Any factors lowering consciousness impair sensory perception. If sensation is incomplete, such as blurred vision, or if past experience is inadequate for understanding stimuli such as pain, the person may react inappropriately to the sensory stimulus.

It is impossible to react to all of the multiple stimuli entering the nervous system. The brain prevents sensory bombardment by discarding or storing sensory information. A person will usually react to stimuli that are the most meaningful or significant at the time. After continued reception of the same stimulus, however, a person stops responding, and the sensory experience goes unnoticed. For example, a person concentrating on reading a good book may not be aware of music in the background.

The balance between sensory stimuli entering the brain and those actually reaching a person's conscious awareness maintains a person's well-being. If an individual attempts to react to every stimulus within the environment, or if the variety and quality of stimuli are insufficient, sensory alterations occur.

Sensory Alterations

The most common types of sensory alterations are sensory deficits, sensory deprivation, and sensory overload. When a patient has more than one sensory alteration, the ability to function and relate effectively within the environment can be seriously impaired.

Sensory Deficits. A loss in the normal function of sensory reception and perception is a **sensory deficit**. The prevalence of sensory deficits is of concern, particularly with the increase in the number of people reaching 65 years and over. As of 2009, 817,000 Canadians had vision loss, with an additional 3.43 million Canadians having diabetic retinopathy, age-related macular degeneration (AMD), cataract, and glaucoma. Vision loss increases in incidence as a person ages. After the age of 40 years, the number of cases of vision loss doubles every decade and triples after 75 years of age (Muzychka, 2009). Vision loss can have different causes at various ages. In Canada, the leading causes of vision loss in children are amblyopia (lazy eye), retinopathy of prematurity (ROP), and congenital causes of diseases such as cataract and glaucoma (Buhmann et al., 2007; in Muzychka, 2009, p. 27). In adults, AMD, glaucoma, diabetic retinopathy, and cataract are the most frequent causes of vision loss (Muzychka, 2009).

Of Canadians 15 years and older, 5.0% reported having a hearing limitation in 2006 (Statistics Canada, 2009). Eight out of ten (83.2%) of these individuals reported having mild hearing limitations, while 16.9% indicated their hearing limitation was severe. Beginning at 35 to 44 years of age, the

prevalence of hearing limitation was at 1.5%. With age, the prevalence increases to 25.9% in individuals aged 75 years and older (Statistics Canada, 2009).

When senses are impaired, the sense of self is affected. Initially, a person may withdraw by avoiding communication or socialization with others in an attempt to cope with the sensory loss. It becomes difficult for the person to interact safely with the environment until new skills are learned. When a deficit develops gradually or when considerable time has passed since the onset of an acute sensory loss, the person may learn to rely on unaffected senses. When one sense is impaired, people depend on their other intact senses. However, individuals with dual sensory impairments, for example, vision and hearing loss, have increased difficulty compensating (Perlmutter et al., 2010).

Patients with sensory deficits may change behaviour in effective or ineffective ways. For example, one patient with a hearing impairment may turn the unaffected ear toward the speaker to hear better, whereas another patient may shun people to avoid the embarrassment of not being able to understand their speech.

Many conditions and diseases cause sensory deficits (Box 47-1). Certain sensory deficits have been found to occur in higher rates with certain genders and race. White people have somewhat higher rates of overall vision loss in Canada compared to visible minorities. Men from visible minority populations have high rates of glaucoma. Aboriginal Canadians have higher rates of diabetic retinopathy. Chinese-Canadians have twice the rate of AMD and diabetic retinopathy compared to Caucasians. Vision loss affects women slightly more than men; however, this may reflect the greater longevity of women (Access Economics, 2009). More research needs to be conducted to identify whether gender and race are the causative factors, or whether other factors such as lifestyle, poverty, inadequate nutrition, genetics, or environment are the causative or associative factors.

Sensory Deprivation. The reticular activating system in the brain stem mediates all sensory stimuli to the cerebral cortex. Even in deep sleep, individuals are able to receive stimuli. Sensory stimulation must be of sufficient quality and quantity to maintain a person's awareness. When a person experiences an inadequate quality or quantity of stimulation, **sensory deprivation** occurs. Three types of sensory deprivation are reduced sensory input (e.g., caused by sensory deficit from visual or hearing loss), elimination of pattern or meaning from input (e.g., exposure to strange environments), and restriction of the environment (e.g., bed rest or reduced environmental variation) that produces monotony and boredom (Touhy et al., 2012).

A decrease in stimuli can occur when patients are placed in isolation. This can reduce the number of people entering their room and contact with the outside world. As well, nurses are required to follow transmission-based precautions, which include the use of masks and gloves. Masks may prevent visualization of caregivers' faces, and gloves will alter the sense of touch. The highly technical nature of health care makes human touch even more important. Patients may feel isolated and anxious when surrounded by equipment and hooked up to machines (Leder & Krukoff, 2008).

Sensory deprivation has many effects (Box 47-2). The symptoms can easily cause nurses and physicians to believe that a patient is psychologically ill and confused, is suffering from severe electrolyte imbalance, or is under the influence of

► BOX 47-1 Common Diseases and Conditions That Cause Sensory Deficits

Visual Deficits

Presbyopia: A gradual decline in the ability of the lens to accommodate or to focus on close objects. Individual is unable to see near objects clearly. Generally associated with aging.

Myopia: A refractive error that is inherited or due to disease or trauma. Most often called nearsightedness.

Cataract: Cloudy or opaque areas in part of or in the entire lens that interfere with passage of light through the lens. Cataracts usually develop gradually and without pain, resulting in blurring, decreased vision, and glare. Although associated with aging, cataracts can also be caused by diabetes, injury, or medications, especially steroids.

Dry eyes: Common in older adults and results in a gritty feeling, pain, itching, blurred vision, light sensitivity, redness and sometimes excessive tears as a compensatory response.

Glaucoma: A condition of increased fluid pressure inside the eye that can eventually damage the optic nerve. Left untreated, can result in visual field loss, decreased visual acuity, a halo effect seen around objects, and blindness. Can be idiopathic in origin or may be caused by eye injury, inflammation, tumours, diabetes, or medications such as steroids. One of the most common causes of blindness. It can develop at any age, but it affects one in 100 Canadians over 40 years of age (Muzychka, 2009).

Diabetic retinopathy: Long-term or poorly managed diabetes can lead to progressive damage to the blood vessels that feed the retina. These blood vessels leak into the retina, resulting in severe vision loss or blindness.

Macular degeneration (also referred to as *age-related macular degeneration [AMD]*): Condition in which the macula (located in the centre of the retina) results in a gradual or sudden loss of central vision. First signs may include blurring of reading matter, distortion or loss of central vision, and distortion of vertical lines.

Retinal detachment: Occurs when the retina develops small holes or tears. May occur with thinning of the retina with aging or from separation of the vitreous from the retina and is more common in those with a family history of retinal detachment. Nearsightedness, infection, or injury, such as trauma to the eye, are other causes (Canadian Ophthalmological Society, 2007).

Hearing Deficits

Conductive hearing loss: Sound waves are not effectively transmitted through the outer and middle ear to the inner ear.

Common causes are partial or total blockage of the ear canal, as from colds, allergies, and ear infections.

Presbycusis: A common progressive hearing disorder in older adults that results in the inability to hear high-pitched sounds, making speech seem more muffled and unclear (Public Health Agency of Canada, 2006).

Central auditory processing disorders: Involve damage to the auditory centres and pathways in the central cortex. Some causes include traumatic brain injury, tumours, or heredity.

Cerumen accumulation: Buildup of cerumen (earwax) in the external auditory canal. Cerumen becomes hard, collects in the canal, and causes conduction deafness. More common in older people.

Otosclerosis: A hereditary condition, resulting in hardening of the ossicles in the middle ear and gradual and progressive hearing loss that is usually accompanied by **tinnitus** (background noises in the ear, hissing or ringing sounds, or discrete tones or pulses).

Menière's disease: A disorder of the inner ear characterized by hearing loss, tinnitus, and **vertigo** (sudden loss of balance). It likely is caused by increased fluid in the inner ear. This disorder usually begins in people between the ages of 20 and 50 years.

Otitis media: Infection of the middle ear; common in infants and children. Recurrent or chronic otitis media can cause damage to the eardrum or middle ear, resulting in permanent hearing loss.

Sensorineural hearing loss: Exposure of ears to excessive noise levels, certain medications, or viruses, that can lead to damage of the hair cells in the cochlea or of the nerve cells between the inner ear and central auditory cortex.

Balance Deficit

Benign positional vertigo: Common condition in older adulthood, usually resulting from vestibular dysfunction. Frequently, episodes of vertigo or disequilibrium are precipitated by a change in the position of the head.

Taste Deficits

Xerostomia: Decrease in salivary production that leads to thicker mucus and dry mouth. It may result from the adverse effects of medications such as antihistamines. Can interfere with the ability to eat and leads to appetite and nutritional problems.

Taste alterations: Alterations, manifested by food aversions and decreased caloric intake; can occur frequently in patients with cancer and as people age.

► BOX 47-2 Effects of Sensory Deprivation

Cognitive Effects

Reduced capacity to learn
Inability to think or to problem solve
Poor task performance
Disorientation
Bizarre thinking
Increased need for socialization, altered mechanisms of attention

Affective Effects

Boredom
Restlessness
Increased anxiety

Emotional lability (i.e., rapid mood swings)

Panic

Increased need for physical stimulation

Perceptual Effects

Alterations in
Visual-motor coordination
Colour perception
Apparent movement
Tactile accuracy
Ability to perceive size and shape
Spatial and time judgement

Source: Adapted from Ebersole, P., Touhy, T., Hess, P., & Jett, K. (2007). *Toward healthy aging: Human needs and nursing response* (7th ed.). St Louis, MO: Mosby Elsevier.

psychotropic drugs. Therefore, you must always be aware of the patient's existing sensory function and the quality of stimuli within the environment. As a nurse, you can help prevent sensory deprivation by ensuring your patients have the necessary visual or hearing aids they require (Aguirre, 2010).

Sensory Overload. When a person receives multiple sensory stimuli and cannot perceptually disregard or selectively ignore some stimuli, **sensory overload** occurs. Excessive sensory stimulation prevents the brain from appropriately responding to or ignoring certain stimuli. It may lead to delirium, a serious condition experienced by many patients who have sensory alterations. Because of the multitude of stimuli leading to overload, the person no longer perceives his or her environment in a way that makes sense. Overload prevents meaningful response by the brain; the person's thoughts race, attention moves in many directions, and anxiety and restlessness may occur. As a result, overload causes a state similar to that produced by sensory deprivation. However, in contrast to deprivation, overload is individualized. A person's tolerance to sensory overload may vary by level of fatigue, attitude, and emotional and physical well-being.

The acutely ill patient may easily be affected by sensory overload. The patient in constant pain or who undergoes frequent monitoring of vital signs or lack of sleep is at risk. Multiple stimuli can combine to cause overload even if you offer a comforting word or provide a gentle back rub. Patients may not benefit from nursing interventions because their attention and energy are focused on more stressful stimuli. Another example is the patient who is hospitalized. Lights are always on. Sounds can be heard from monitoring equipment, staff conversations, equipment alarms, and the activities of people entering the unit.

The behavioural changes associated with sensory overload can easily be confused with mood swings or simple disorientation. You must look for symptoms such as racing thoughts, scattered attention, restlessness, and anxiety. Constant reorientation, control of excessive stimuli, and, if possible, providing care in blocks of time become an important part of the patient's care. Providing clocks and calendars, dimming lights, family support, and clear communication can help to prevent sensory overload and delirium (Robinson et al., 2008).

Nursing Knowledge Base

Factors Affecting Sensory Function

Many factors affect sensory function, including the patient's age, the quantity and quality of stimuli, social interaction, and family and environmental factors. As the nurse delivering care, you must be aware of and address as many of these factors as possible.

Age. Infants are unable to discriminate sensory stimuli because nerve pathways are immature. Visual changes during adulthood include presbyopia, which leads to the need for reading glasses. These changes usually occur from ages 40 to 50 years. Visual difficulties normally associated with aging include reduced visual fields, increased glare sensitivity, impaired night vision, reduced accommodation and depth perception, and reduced colour discrimination (Speros, 2009) (Box 47-3). Colours with short wavelengths, such as blues, pinks, beiges, and greens, become more difficult to distinguish, while colours with long wavelengths, such as reds, oranges, and yellows, are easier to discriminate. The visual changes can occur gradually, and in many cases the older adult may not

> BOX 47-3

Aging Changes to Vision That Affect Visual Ability

- Decrease in peripheral vision
- Shrinkage in the size of the pupils
- Ciliary muscles that change the shape of the lens become less flexible
- Cornea becomes more opaque and yellowed
- Decrease in tear production
- Clouding of the lens

> BOX 47-4

Aging Changes to Hearing That Affect Hearing Ability

- Increased rigidity of the ossicles
- Decreased elasticity of the tympanic membrane
- Increased cerumen production
- Decrease in number of neurons and blood vessels
- Loss of hair cells in inner ear

notice their vision deteriorating until a triggering event occurs, such as a fall.

Hearing changes include decreased hearing acuity, speech intelligibility, pitch discrimination, and hearing threshold (Box 47-4). Older adults hear low-pitched sounds best but have difficulty hearing conversation over background noise. Speech sounds are garbled, and reception of and reaction to speech are delayed. Older adults have difficulty discriminating particular consonants (*z, t, f, g*) and high-frequency sounds (e.g., *s, sh, ph, k*) (presbycusis). A problem with age-related hearing loss is that some individuals may not even be aware of their deficit, or that what are thought of as age-related changes are, in fact, abnormal changes. A serious concern for those with a hearing deficit is that they may be inappropriately labelled as confused.

Noise exposure over time and loss of blood supply to the cochlea affect hearing loss as people age. Adult sensorineural hearing loss can be caused by metabolic, vascular, and other systemic alterations. Metabolic changes, however, appear to be the most significant factor affecting age-related hearing loss (Sprinzel & Riechelman, 2010). Hearing loss may also be a side effect of medications, such as thiazide diuretics. A patient may benefit from a referral to an **audiologist** or **otolaryngologist** if the assessment reveals a serious hearing problem.

Harmful noise levels occur in the workplace and in recreational environments. Poor noise control, inadequate hearing protection, and lack of education about the risks of hearing loss are contributing factors. Military personnel, lawn care workers, and people who work around power tools and loud music are at risk for occupation-related hearing loss (Fausti et al., 2005).

Olfactory changes include a reduction in olfactory nerve fibres by the age of 50 years. Reduced taste discrimination and reduced sensitivity to odours are common. By age 65, more than half of people report a change in sense of smell, resulting in decreased enjoyment of eating and drinking, as well as posing a safety risk for detecting harmful odours in the environment. Diminished sense of smell results from a reduction in the number of olfactory sensory neurons and bulb cells.

Disorders such as Parkinson's, Alzheimer's, and trauma can also cause a diminished sense of smell (Griggs, 2008).

Diminished taste with aging likely results from a reduction in the function or number of taste buds along with decreased saliva production. Smoking, poor oral hygiene, nasal polyps, and radiation therapy may also contribute to diminished taste sensation (Capezuti et al., 2008). Medications and their adverse effects can contribute to gustatory changes. Some of the common medications that can cause gustatory changes are lipid-lowering drugs, antihistamines, antibiotics, bronchodilators, and antidepressants (Griggs, 2008).

Proprioceptive changes after the age of 60 years include increased difficulty with balance, spatial orientation, and coordination. Proprioceptive dysfunction can be caused by vestibular dysfunction and neuropathy, or any factor that affects the reception, transmission, perception, or interpretation of proprioceptive stimuli (McCance & Huether, 2006). Older adults experience tactile changes, including declining sensitivity to pain, pressure, and temperature. Factors affecting tactile changes are numerous and include trauma, infection, metabolic or vascular changes, degenerative diseases, and sedative drugs (McCance & Huether, 2006).

It is very important to note, you must be careful not to assume automatically that a patient's sensory problem is related to advancing age. You must conduct a careful assessment to determine the true cause(s).

Quality of Stimuli. Meaningful stimuli reduce the incidence of sensory deprivation. In a patient's home or a long-term care facility, meaningful stimuli may include such things as pets, music, television, family photographs, a calendar, and a clock. The presence of others can offer positive stimulation. The presence or absence of meaningful stimuli influences alertness and the ability to participate in care.

Quantity of Stimuli. The quantity of stimuli, whether excessive or minimal, can have detrimental effects on the patient. Excessive stimuli in an environment can cause sensory overload. The frequency of observations and procedures performed in an acute care setting may be stressful. If the patient is in pain, has many tubes and dressings, overstimulation can be a problem. As well, the sounds of electrical monitors and equipment, repetitive or loud noises, such as an elevator or the nurses' station nearby, bright lighting, and the odour of body fluids are other examples of stimuli that can contribute to overload.

Social Interaction. Patients with hearing loss tend to decrease the time spent with social activities and verbal communication. Family members may notice a reluctance to use the telephone and that questions are being answered inappropriately. Children with hearing deficits may be inattentive, uncooperative, or easily bored. Often a patient is too embarrassed to continually ask another person to repeat what has been said; instead, the person avoids communication. Patients who find their lifestyles influenced by hearing or vision loss can become at risk for lowered self-esteem, depression, and social withdrawal (Pelletier et al., 2009).

Family Factors. The amount and quality of contact with supportive family members and significant others can influence the degree of isolation the patient feels. The absence of visitors during hospitalization or residency in a long-term care facility can also affect sensory status. This is a common problem in hospital settings, where visitation is restricted. The ability to discuss fears or concerns with loved ones is an important coping mechanism for most people. Therefore, the absence of

meaningful conversation can cause a person to become sensorially deprived, and you may not be alerted to this problem until behavioural changes occur.

Environmental Factors. A person's work environment can increase the risk for sensory alterations. Individuals who are exposed to loud noises at work or who have occupations involving the risk of exposure to chemicals or flying objects should be screened for hearing and visual problems. Patients who use their hands in a repetitive fashion (e.g., computer programmers) are at risk for carpal tunnel syndrome, a condition characterized by swelling or inflammation of the wrists. This inflammation creates pressure on the nerve as it passes through the narrow area in the wrist. The patient can experience numbness, tingling, pain, and weakness in the hand while performing fine hand movements.

A hospitalized patient can be at risk for sensory alterations from exposure to environmental stimuli or a change in sensory input. Patients who are immobilized because of bed rest, disability, or physical encumbrances (e.g., casts or traction) are at risk because they are unable to move freely and to seek out meaningful interactions. Patients placed in isolation because they have a communicable disease are also at risk (see Chapter 32) because of a lack of interaction with visitors.

As a result of illness or hospitalization, a patient is often confined to an unfamiliar environment. This does not mean that all hospitalized patients have sensory alterations. However, you must carefully assess patients who are subjected to continued sensory stimulation. The patient's environment, within both the health care setting and the home, is carefully assessed, looking for factors that pose risks or that need adjustment to provide safety and more stimulation.

Critical Thinking

Critical thinking involves synthesizing knowledge and information gathered from patients, experience, and intellectual and professional standards. During assessment (Figure 47-1), you consider all critical thinking elements that help you make appropriate nursing diagnoses. Rowles and Russo (2009) discuss how nurses need critical thinking skills to provide individualized, evidence-informed care to meet patients' complex needs. Critical thinking requires interpreting and synthesizing information to make decisions in planning and delivering nursing care.

In caring for patients with sensory alterations, you must integrate knowledge from several areas: normal anatomy and physiology of the sensory and nervous systems, the pathophysiology of sensory deficits and factors that affect sensory function, therapeutic communication principles, and normal aging changes. This information enables you to conduct appropriate assessments, anticipate what to recognize when a patient describes a sensory problem, and recognize abnormalities. For example, knowing that someone with glaucoma will have tunnel vision (i.e., they can see clearly at the centre of their visual field but cannot see the periphery), will help you recognize that when they are sitting down for a meal, they may not see the location of their cup or other dining utensils that would be outside the centre of their vision.

Previous experience in caring for patients with sensory deficits enables you to recognize limitations in function in each new patient and how those limitations might affect the patient's ability to carry out daily activities. For example, after caring for a patient with a hearing impairment, you will

Figure 47-1 Critical thinking model for sensory alterations assessment.

be able to conduct a more effective assessment of the next patient.

Critical thinking qualities and standards, when applied during assessment, ensure a thorough and accurate database from which to make decisions.

Standards of care and practice, such as those from the Canadian Ophthalmological Society, the Registered Nurses' Association of Ontario, the Canadian Gerontological Nursing Association, and the Canadian National Institute for the Blind (CNIB) provide criteria for screening sensory problems and for establishing standards for competent, safe, and effective care and practice. Using critical thinking, you can conduct a thorough assessment and then plan, implement, and evaluate care that will enable the patient to function safely and effectively.

Nursing Process

◆ Assessment

When assessing patients with or at risk for sensory alterations, you must consider how the patient's particular illness may lead or has led to sensory changes. As well, all the factors that may influence sensory function must be considered. For example, if the patient has a hearing impairment, communication style is adjusted and assessment is focused on relevant criteria related to hearing deficits. You collect a history that also assesses the patient's current sensory status and the

degree to which a sensory deficit affects the patient's lifestyle, psychosocial adjustment, developmental status, self-care ability, and safety. The assessment must also focus on the quality and quantity of environmental stimuli.

Sensory Alterations History

The nursing health history includes assessment of the nature and characteristics of sensory alterations or any problem related to an alteration. Begin by asking the patient to describe the sensory deficit, as in the following examples:

- Describe your hearing loss. For how long have you noticed this?
- Describe how your vision is affected.
- Explain how use of your hands has changed.

Knowledge about the onset and duration of the sensory alteration can be helpful. You can learn how long the patient has taken measures to adjust to the alteration by asking questions such as the following:

- How long have you had a visual problem?
- When did you begin to feel numbness in your hands? In your legs?
- How long have you noticed being unable to hear conversations clearly?

It is also useful to assess the patient's self-rating for a sensory deficit. You can simply say, "Rate your hearing as excellent, good, fair, poor, or bad." Then, from the patient's self-rating, explore more fully the patient's perception of a sensory loss. This provides a more in-depth look at how the patient's quality of life has been influenced. There are a number of bedside assessment tools that can be used to assess hearing impairment. A screening tool developed by Ventry and Weinstein (1982) has been found to be effective in identifying patients needing audiological intervention. The screening version of the Hearing Handicap Inventory for the Elderly (HHIE-S) is a 5-minute, 10-item questionnaire designed to assess how a patient perceives the emotional and social effects of hearing loss. The greater the handicapping effect from the hearing loss, the higher the score (Stark & Hickson, 2004). The Minimum Data Set (MDS) assessment can be used at admission and on a regular basis to detect conductive, sensorineural, or mixed hearing loss (Adams-Wendling & Pimple, 2008).

Regarding vision assessment, a vision screening kit was adapted by Hawranik and Bell (2007), from the Centre of Eye Research Australia (CERA) and World Health Organization (Carnicelli, 2001), to meet North American vision assessment conversions. The vision screening kit contains a referral algorithm and vision test results, vision history forms, a pinhole mask, and vision cards for distance and near vision testing (Figure 47-2). The referral algorithm provides direction for referral to an optometrist, ophthalmologist, or general practitioner or for vision screening in one year. The tool is useful for seniors with speech, cognitive, and motor impairments and those who are not fluent in English.

A health history can also reveal any recent changes in a patient's behaviour. Often friends or family are the best resources for this information because the patient may be unaware of any change. Asking the following questions may be helpful:

- Have you noticed any change in their hearing (e.g., television being turned louder)?
- Has your family member or friend shown any recent mood swings (e.g., outbursts of anger, nervousness, fear, or irritability)?

Figure 47-2 A vision screening kit. **Source:** Courtesy Sandy Bell, Winnipeg, MB.

- Have you noticed him or her avoiding social activities?
- Has your mother fallen recently?

It is important to remember that many adults are sensitive about admitting losses and may hesitate to share information.

Mental Status

Mental status assessment is an important component of any evaluation of sensory function. This is particularly important as visual impairment is a risk factor for cognitive decline (Whitson et al., 2007). Visual impairment can be associated with hallucinations, a condition referred to as Charles Bonnet syndrome (Jackson & Ferencz, 2009; Pelletier et al., 2009). Approximately 10% to 37% of people with vision loss are thought to have Charles Bonnet syndrome associated with vision loss (Jackson & Ferencz, 2009).

Observing the patient during history-taking, physical examination, and nursing care provides valuable data for evaluation of a patient's mental status. An assessment of mental status is valuable particularly if you suspect sensory deprivation or overload. Observe the patient's physical appearance and behaviour, measure the patient's cognitive ability, and assess the patient's emotional status. The Mini-Mental State Examination is an example of a tool that can be used to measure disorientation, altered conceptualization and abstract thinking, and change in problem-solving abilities (see Chapter 31). For example, a patient with severe sensory deprivation may not be able to carry on a conversation, remain attentive, or display recent or past memory.

If the patient resides in his or her own home, check for cleanliness in the home, spoiled food on the counter or in the fridge, misplaced items, inappropriate dress, and losing the way to the store or other locations he or she used to frequent.

Physical Assessment

To identify sensory deficits and their severity, assess vision, hearing, olfaction, taste, and the ability to discriminate light touch, temperature, pain, and position. Chapter 31 describes assessment techniques in detail. Table 47-2 summarizes assessment techniques for identifying sensory deficits. The data will be more accurate if the examination room is private, quiet, and comfortable for the patient.

You will also rely on personal observation of the patient to detect sensory alterations. Some useful observations indicating

hearing loss are the following: the patient seems inattentive to others, responds with inappropriate anger when spoken to, believes people are talking about him or her, has trouble following clear directions, asks to have something repeated, has monotonous voice quality and speaks unusually loudly or softly, has the television unusually loud, and answers questions inappropriately (Touhy et al., 2012).

The typical physical tests used to screen for hearing impairment rely on an examiner's whispered voice or a tuning fork. The Welch Allyn AudioScope is very effective for measuring hearing acuity. The hand-held instrument includes an ear speculum that is placed within the external ear canal. The examiner can view the tympanic membrane to ensure that cerumen is not blocking the canal. A tonal sequence is initiated by pressing a button on the audioscope. The instrument is highly sensitive to detecting hearing loss.

Ability to Perform Self-Care

Patients' functional abilities in their home environment or health care setting, including feeding, dressing, grooming, and toileting, should be assessed. For example, you can assess whether a patient with altered vision can find items on a meal tray and can read directions on a prescription. Vision loss contributes to an increase in self-administered medication errors and increased rates of hospitalization (Pelletier et al., 2009). As well, you should determine a visually impaired patient's ability to perform daily routines such as reading bills, writing cheques, or driving a vehicle at night. Does a patient's loss of balance prevent rising from a toilet seat safely? Any impairment in the ability to perform self-care has implications for planning discharge from a health care setting and for providing resources within the home. Vision loss with older people increases the risk of falls and the likelihood of being institutionalized (Pelletier et al., 2009).

Health Promotion Habits

You must assess the daily routines that patients follow to maintain sensory function. What type of eye and ear care is incorporated into daily hygiene? For those individuals who participate in sports or recreational activities or who work in a setting where ear or eye injury is a possibility (e.g., chemical exposure or constant exposure to loud noise), determine if safety glasses or hearing protective devices (HPDs) are worn. Do patients who use assistive devices such as eyeglasses, contact lenses, or hearing aids know how to care for them (see Chapter 37)? Are the devices used? Are they in proper working order?

Assess the patient's adherence to routine health screening. When was the last time the patient had an eye examination or hearing evaluation? For adults, routine screening of visual and hearing function is imperative to detect problems early. All older adults should be screened for auditory and visual deficits (Capezuti et al., 2008). This is especially true for glaucoma, which can lead to permanent visual loss if undetected. Recommended screening guidelines are usually structured according to age. Research indicates a lack of attention to vision care in long-term care settings. Hawranik and Bell (2007) surveyed 28 nursing homes in Winnipeg, Manitoba, and 45 in Aberdeen, Scotland, to determine the nature of their vision care services and data collection methodologies for falls and fractures. Only six facilities in Winnipeg and one in Aberdeen indicated they had either a policy or procedure on vision care services. Most of the health records did not indicate whether the elderly

► TABLE 47-2 Assessment of Sensory Function

Assessment	Behaviour Indicating Deficit (Children)	Behaviour Indicating Deficit (Adults)
Vision* Ask patient to read newspaper, magazine, or lettering on menu. Measure visual acuity with Snellen chart (see Chapter 31) or the Vision Screening Tool. Assess visual fields and depth perception. Assess pupil size and accommodation to light. Ask patient to identify colours on colour chart or crayons.	Self-stimulation, including eye rubbing, body rocking, sniffing or smelling, arm twirling; hitching (using legs to propel while in sitting position) instead of crawling	Poor coordination, squinting, underreaching or overreaching for objects, persistent repositioning of objects, impaired night vision, accidental falls
Hearing Perform conventional assessment, including whisper and tuning fork (see Chapter 31). Perform audiometry, if indicated. Observe patient conversing with others. Compare patient's ability to recognize consonants with ability to distinguish vowels. Assess patient's perception of hearing ability and history of tinnitus. Inspect ear canal for hardened cerumen.	Frightened when unfamiliar people approach, no reflex or purposeful response to sounds, failure to be awakened by loud noise, slow or absent development of speech, greater response to movement than to sound, avoidance of social interaction with other children	Blank looks, decreased attention span, lack of reaction to loud noises, increased volume of speech, positioning of head toward sound, smiling and nodding of head in approval when someone speaks, use of other means of communication such as lip-reading or writing, complaints of ringing in ears
Touch Assess patient for sensitivity to light touch (see Chapter 31) and temperature. Check patient's ability to discriminate between sharp and dull stimuli. Assess whether patient can distinguish objects (coin or safety pin) in the hand with eyes closed. Ask whether patient feels unusual sensations.	Inability to perform developmental tasks related to grasping objects or drawing, repeated injury from handling of harmful objects (e.g., hot stove, sharp knife)	Clumsiness, overreaction or underreaction to painful stimulus, failure to respond when touched, avoidance of touch, sensation of pins and needles, numbness
Smell Ask patient to close eyes and identify several nonirritating odours (e.g., coffee, vanilla).	Difficult to assess until child is six or seven years old, difficulty discriminating noxious odours	Failure to react to noxious or strong odour, increased body odour, decreased sensitivity to odours
Taste Ask patient to sample and distinguish different tastes (e.g., lemon, sugar, salt). Have patient drink or sip water and wait one minute between each taste. Ask patient if recent weight change has occurred.	Inability to tell whether food is salty or sweet, possible ingestion of strange-tasting things	Change in appetite, excessive use of seasoning and sugar, complaints about taste of food, weight change
Position Sense Perform conventional tests for balance and position sense (see Chapter 31).	Clumsiness, extraneous movement, excessive arm swinging in those with hyperactivity or learning difficulty Inability to sit or stand as per expected milestones	Poor balance and spatial orientation, shuffling gait, reduced response to brace self when falling, more precise and deliberate movements

*Go to <http://www.cnlb.ca/en/about/publications/vision-health/lwl/default.aspx> to see pictures of what individuals with varying visual impairments might see.

resident wore glasses or when their last eye appointment had taken place.

Hazards

A patient with sensory alterations is at risk for injury if the living environment is unsafe. For example, a patient with visual impairment cannot see potential hazards clearly. A patient with proprioceptive problems may lose balance easily

and fall. The condition of the home, the rooms, and the front and back entrances can be problematic for the patient with sensory alterations. Some of the more common hazards are the following:

- Uneven, cracked walkways leading to front or back door
- Doormats with slippery backing
- Extension and telephone cords in the main route of walking traffic

- Loose area rugs on hardwood floors or tiles; runners placed over carpeting
- Bathrooms without shower or tub grab bars
- Water faucets unmarked to designate hot and cold
- Bathroom floor with slippery surface
- Absence of smoke detectors in rooms
- Unlit stairways, lack of handrails
- Floors cluttered with material and excessive furniture, including footstools
- Kitchen equipment (e.g., ranges, irons, toasters) with hard-to-read settings

Patients living with visual impairment may also be unable to read medication labels and syringe gauges. Therefore, ask the patient to read a label to determine whether he or she can adequately see the instructions. If a patient has a hearing impairment, check to see whether the sounds of a doorbell, telephone, smoke alarm, and alarm clock are easy to discriminate.

In the hospital environment, caregivers often forget to rearrange furniture and equipment to keep paths from the bed and chair to the bathroom and entrance clear. Walking into a patient's room and looking for safety hazards must be a routine part of your care. Check frequently for the following:

- Is the call light within easy, safe reach?
- Are intravenous (IV) poles on wheels and easy to move?
- Are footstools against the bed?
- Are suction machines, IV pumps, or drainage bags positioned so that a patient can rise from a bed or chair easily?

Communication Methods

To understand the nature of a communication problem, you must know whether a patient has trouble speaking, understanding, naming, reading, or writing. Patients with existing sensory deficits often develop alternative ways of communicating. A deaf or hearing-impaired patient may read lips, use sign language, listen with the help of a hearing aid, or read and write notes. For someone who is hearing impaired, speak clearly with a moderate rate of speech and pause to determine understanding. Ensure you sit at eye level so that the patient with hearing impairment can communicate.

Horton-Ikard and Muñoz (2010) identify challenges when working with culturally and linguistically diverse individuals, such as the following: (1) health care providers with insufficient knowledge for working with people with language barriers; (2) difficulty distinguishing language differences from language disorders; and (3) lack of confidence and competence in culturally sensitive assessments and treatments. Try to include family members who can assist with translation or obtain assistance from a translator.

Visually impaired patients may be unable to observe facial expressions and other nonverbal behaviours that clarify the content of spoken communication. Instead, they rely on voice tones and inflections to detect the emotional tone of communication. Patients who have visual impairments may learn to read Braille, although decreased tactile acuity of the fingers may make this more difficult in older people. If the person has a visual impairment, speak normally from a reasonably close distance and ensure that lighting is sufficient.

Social Support

It is important for you to know the patient's social skills and level of satisfaction with the support given by family and friends. Is the patient satisfied with the support made available

BOX 47-5 RESEARCH HIGHLIGHT

An Assistive Device May Be Viewed as a Stigma of Dependency

Research Abstract

A study examining the experience of informal caregivers caring for their family member found that the older adult had a "desire for independence." The older adult would insist on maintaining his or her independence despite cognitive or physical limitations. One daughter described the following: "Under protest, she got a walker. It's sitting folded up behind her TV covered with a blanket. She also refuses to use her cane. She's very wobbly and for a long time I would grab her arm when we were walking and she would grab it away" (Hawranik & Strain, 2007, p. 164).

Reference: Hawranik, P., & Strain, L. (2007). Giving voice to informal caregivers of older adults. *Canadian Journal of Nursing Research*, 39(1), 156–172.

from friends? Is the patient able to solve problems with family members? Does the family offer the support needed when the patient requires assistance as a result of a sensory loss? The long-term effects of sensory alterations can influence family dynamics and a patient's willingness to remain active in society. People with sensory impairments, particularly visual and hearing impairments, may withdraw from social interaction and activities. Connecting seniors with sensory impairments to community resources can assist in preventing social isolation, depression, and cognitive decline (Capezuti et al., 2008).

Use of Assistive Devices

Assess for the use of assistive devices (e.g., hearing aids or glasses) and the sensory effects for the patient. This includes learning how often the devices are used daily, the patient's or family caregiver's method for cleaning, and the patient's knowledge of what to do when a problem develops. However, just because the patient has an assistive device, do not assume that it works or that the patient uses it or benefits from it (Box 47-5).

Other Factors Affecting Perception

Factors other than sensory deprivation or overload may cause impaired perception (e.g., medications or pain). Assess the patient's medication history, which includes prescribed and over-the-counter medications, as well as herbal products and caffeine. This history includes gaining information regarding the frequency, dose, method of administration, and last time these medications were taken. Some antibiotics (e.g., streptomycin, gentamicin, and tobramycin) are **ototoxic** and can permanently damage the auditory nerve; chloramphenicol can irritate the optic nerve. Opioid analgesics, sedatives, and antidepressant medications can alter the perception of stimuli. Conduct a thorough pain assessment when pain is suspected to be causing perceptual problems (see Chapter 41).

Patient Expectations

Patients depend on their senses to provide them with information so as to respond or react to a specific situation or problem. Therefore, patients may expect caregivers to recognize and

appropriately manage and adjust their environment to meet their sensory needs. This would include assisting the patient in adapting his or her lifestyle as a result of sensory impairment. You should determine from patients exactly what they expect to achieve and what interventions have been helpful in the past in the management of their limitations.

❖ Nursing Diagnosis

After assessment, you need to review all available data and look for patterns and trends suggestive of a health problem relating to sensory alterations (Box 47-6). For example, a patient's advanced age, inattentiveness during conversations, and self-rating of hearing as "poor" are all defining characteristics for the nursing diagnosis of *disturbed sensory perception (auditory)*. Validate your findings to ensure the accuracy of the diagnosis. For example, the diagnosis of disturbed thought processes could mistakenly be made if you do not confirm the patient's hearing deficit and perception of poor hearing.

As well, determine the factor that likely causes the patient's health problem. In the previous example, impacted cerumen is the cause of the patient's hearing alteration. The etiology or related factor of a nursing diagnosis is a condition that can be affected by nursing interventions. The etiology must be accurate; otherwise, nursing therapies will be ineffective. For a patient with impacted cerumen, regular irrigation of the ear canal has the potential to improve auditory perception (Armstrong, 2009). In contrast, if the patient's auditory alteration were related to hearing loss from nerve deafness, nursing interventions for alternative communication methods would be necessary.

The patient may also have health care problems for which sensory alteration is the etiology, such as with the diagnosis of risk for injury. People with vision loss have double the

incidence of falls and double the incidence of difficulties in daily living compared with those without vision loss (National Coalition for Vision Health, 2011). You may also select nursing diagnoses by recognizing the way that sensory alterations affect a patient's ability to function (e.g., self-care deficit). In addition, most patients present themselves to health care providers with multiple diagnoses (Figure 47-3). In the example of the concept map, a patient with retinal detachment has the nursing diagnosis of disturbed sensory perception, which can lead to risk for falls and fear. You must recognize patterns of data that reveal health problems created by the patient's sensory alteration. Examples of nursing diagnoses that might apply to patients with sensory alterations are the following:

- *Impaired adjustment*
- *Impaired verbal communication*
- *Risk for injury*
- *Impaired physical mobility*
- *Self-care deficit, including bathing or hygiene, dressing or grooming, or toileting*
- *Situational low self-esteem*
- *Disturbed sensory perception*
- *Social isolation*
- *Disturbed thought processes*
- *Altered socialization*

❖ Planning

During planning, use your critical thinking skills to synthesize information from multiple sources (Figure 47-4), including knowledge gained from the assessment and knowledge of how sensory deficits affect normal functioning. In this way, you can recognize the extent of the patient's deficit and know the type of interventions most likely to be helpful. Also consider the role that other health care providers can play in planning care and the available community resources (e.g., CNIB) that may be useful. Previous experience in caring for patients with sensory alterations can be invaluable when planning nursing approaches.

When applying critical thinking to planning care, professional standards can be particularly useful. These standards, in the form of clinical pathways or clinical practice guidelines, often recommend interventions based on research evidence for the patient's condition. For example, patients who have visual deficits and are hospitalized may be placed on a fall prevention protocol that will incorporate research-based precautions to ensure patient safety.

Goals and Outcomes

During planning, you will develop an individualized plan of care for each nursing diagnosis (Box 47-7). With the patient, develop a realistic plan that incorporates what you know about the patient's sensory problems and the extent to which sensory function can be maintained or improved. If maintenance or improvement is not realistic, preventing injury and learning alternative ways of maintaining independence are key. Goals and outcomes should be realistic and measurable. A goal of care for a patient with an actual or potential sensory alteration may be this: "The patient will regain improvement in hearing acuity within two weeks." Associated outcomes for this goal might be the following:

- The patient will report using communication techniques for improved reception of messages within two weeks.

► BOX 47-6 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Assess patient's visual acuity.	Has reduced ability to see objects clearly. Needs brighter light to read. Has trouble distinguishing edges of stairs. May have fallen or have had a recent fracture.	<i>Risk for injury related to visual impairment from cataract formation</i>
Visit home setting and inspect for any hazards that may pose risks to patient.	Lighting in rooms, hallways, and stairwells is very dim. Carpet in living room is old, and edges are curled up. Steps lead up to front entrance of home.	
Review medical record from clinic visit.		

Figure 47-3 Concept map for patient with retinal detachment of right eye after blunt injury to forehead. *ADLs*, Activities of daily living; *IADLs*, instrumental activities of daily living.

- The patient will successfully demonstrate the technique for cleansing the hearing aid within one week.
- The patient and family will be observed using proper communication skills to send and receive messages.
- The patient will self-report improved hearing acuity.

Setting Priorities

Priorities of care must be set with regard to the type and extent of sensory alteration that affects a patient. For example, a patient who enters the emergency department after experiencing eye trauma may have priorities of reducing anxiety and preventing further injury to the eye. In contrast, a patient who is being discharged from an outpatient surgery department following cataract removal may have the priority of learning about any self-care requirements. However, safety is always a top priority. The patient can also help prioritize aspects of care. For example, patients may wish to learn ways to communicate more effectively or to participate in favourite hobbies, given their sensory limitation.

Some sensory alterations are short term (e.g., a patient suffering sensory or perceptual alterations as a result of sensory overload in an ICU). Appropriate interventions are thus likely to be temporary (e.g., frequent reorientation or introduction of intimate and pleasant stimuli, such as a back rub). Sensory alterations such as permanent visual loss require long-term goals of care for patients to adapt. However, patients who have sensory alterations at the time of entering a health care setting are usually most informed about how to adapt interventions to their lifestyles. People with sensory impairment need to control whatever part of their care they can. Sometimes it

becomes necessary for the patient to make major changes in self-care activities, communication, or socialization.

Collaborative Care

When developing a plan of care, consider all resources available to patients. The family can play a key role in providing meaningful stimulation and learning ways to help the patient adjust to any limitations. As part of a multidisciplinary health care team, you may also refer the patient to other health care providers. Early referrals to occupational or speech therapists, for example, can speed a patient's recovery. If a patient has experienced a major loss of sensory function and is also unable to manage medical needs, such as medication self-administration or dressing changes, referral to home care may be an option. Numerous community-based resources (e.g., CNIB, Canadian Association of Independent Living Centres, or the Canadian Hearing Society) are also available. You may be able to arrange a volunteer to visit a patient or have printed materials made available that describe ways to help cope with sensory problems.

Implementation

Nursing interventions involve the patient and family so that a safe, pleasant, and stimulating sensory environment can be maintained. The most effective interventions enable the patient with sensory alterations to function safely with existing deficits and to continue a normal lifestyle. Learning to adjust to sensory impairments can occur at any age with proper support and resources.

Figure 47-4 Critical thinking model for sensory alterations planning.

Health Promotion

Good sensory function begins with prevention. Almost everyone becomes exposed to risks in the environment that may cause sensory alterations. When patients enter primary health care settings, you can take the opportunity to review common-sense approaches for reducing the risk of sensory loss (Box 47-8).

Screening. The WHO (2010) estimates that 285 million people worldwide have visual impairment. More than 4 million Canadians have an age-related eye disease, such as age-related macular degeneration (AMD), glaucoma, diabetic retinopathy, or cataracts (National Coalition for Vision Health, 2011). Vision loss is among the most costly of chronic diseases in Canada. Ranking fourth in prevalence among diagnostic categories, it poses a greater burden in direct and indirect costs than respiratory diseases, diabetes, mental disorders, and many others. Measured in direct health related costs, vision loss ranks higher than any disease category in Canada (Muzychka, 2009).

Preventable blindness is a worldwide health issue. Therefore, prevention of visual impairment begins with children and requires appropriate screening (Hockenberry & Wilson, 2007). Three recommended interventions are (a) screening for rubella or syphilis in women who are considering pregnancy; (b) adequate prenatal care to prevent premature birth (with the danger of exposure of the infant to excessive oxygen); and (c) periodic screening of all children, especially newborns through preschoolers, for congenital blindness and visual impairment caused by refractive errors, amblyopia (loss of visual acuity in the nondominant eye because of lack of use in childhood), and **strabismus** (misalignment of the eyes) (Box 47-9).

Visual impairment is common during childhood. The most common visual problem is a **refractive error** such as nearsightedness. Parents must know signs suggesting visual impairment (e.g., failure to react to light and reduced eye contact from the infant) and should be instructed to report these signs to a physician immediately. Vision screening of school-aged children and adolescents can detect problems early. The school

BOX 47-7 NURSING CARE PLAN

Disturbed Sensory Perception

Assessment

Judy Long, a 70-year-old retired receptionist, tells the community health nurse that her vision has become progressively blurred over the last several years. She comments that she is having her neighbour drive her places. Judy visited an ophthalmologist, and surgery is planned.

Assessment Activities

Ask Judy to describe her vision changes.

Ask Judy to describe any life changes that have occurred since the change in vision.

Assess Judy's visual acuity.

Findings and Defining Characteristics

Judy states, "My left eye seems to have a film over it that makes my vision blurred. I am having difficulty reading. I also have difficulty with night driving; the headlights are large and blurred."

Judy indicates that she has always managed her home and done volunteering. She says she is losing her independence because she has to have someone drive her, and she is now hesitant to use stairs at home.

Judy cannot read the Snellen chart with the left eye.

Continued

► BOX 47-7 NURSING CARE PLAN—cont'd

Assessment Activities

Ask Judy the results of the visit to the ophthalmologist.

Conduct a home hazard assessment.

Findings and Defining Characteristics

Judy states that she was told she has a cataract in the left eye and a cataract beginning in her right eye; surgery is planned on her left eye.

The home is cluttered, the lighting is dim, and the stairs going into the house have no handrails.

Nursing Diagnosis: Disturbed sensory perception related to altered sensory reception of senile cataract.

Planning

Goals (Nursing Outcomes Classification)*

Judy will maintain independence in a safe home environment.

Judy will make the best use of existing visual function.

Expected Outcomes

Safety Behaviour: Home Physical Environment

Judy will verbalize changes made to protect and maintain visual acuity for indoor and outdoor activities in two weeks. A safety check of her home will show removal of safety hazards in one week.

Judy will explain plans for alternative transportation to work and social activities in one week.

Sensory Function: Vision

Judy will use visual aid devices in one week.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]

Environmental Management

Teach Judy how to improve the safety of her environment, such as making sure her home is free of clutter, footstools, and electrical cords, and to avoid rearranging furniture.

Instruct Judy to reduce glare by wearing dark-coloured sunglasses outside.

Teach Judy to use a light over the shoulder for reading and writing.

Provide magnifier for Judy to use to read newspaper and mail.

Rationale

Keeping the area clutter free reduces the risk of injury (Campbell et al., 2005).

Patients have better visual acuity when they protect their eyes from bright light (Ebersole et al., 2007).

People with cataracts see better with wider illumination (Ebersole et al., 2007).

Devices will provide magnification to improve visual acuity.

Emotional Support

Encourage Judy to express feelings regarding loss of vision and lifestyle changes.

People with vision loss experience triple the incidence of depression compared with those without vision loss (National Coalition for Vision Health, 2011).

Family Involvement

Confer with Judy on selecting a family member, friend, or community resource person who can provide transportation until after the eye condition has been corrected.

An alternative means of transportation will foster safety.

[†]Intervention classification labels are from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Ask Judy to describe the changes that have made the home environment safer.

Patient Response and Finding

Judy responds that the family has removed the clutter and handrails have been placed at the entryway. Lighting has been placed behind her chair, and 100-watt lights are in the living room.

Achievement of Outcome

Judy reports feeling safer walking the stairs and moving about in her home. The home hazards have been reduced.

► BOX 47-7 NURSING CARE PLAN—cont'd

Nursing Actions	Patient Response and Finding	Achievement of Outcome
During a home visit, observe the home environment for safety hazards.		
Observe Judy's verbal and nonverbal responses to the lifestyle adaptations.	Judy says, "I feel safer when walking in my home."	
As Judy uses a magnifier, have her read a medication label.	Judy is able to read the name of her medication and dosage correctly.	Better use is made of current vision.
Ask Judy if she is able to maintain a degree of independence with the environmental and lifestyle modifications.	Judy states, "I am more independent at home, and until surgery, I do not mind someone driving for me."	Judy has attained some degree of independence.
Ask Judy to identify source of transportation.	Judy says a family member has agreed to drive her shopping and for surgery.	Judy has transportation through the weeks required for the surgical experience.

* BOX 47-8

FOCUS ON PRIMARY HEALTH CARE

Sensory Alterations

The major goals in primary health care settings are health promotion, disease prevention, early detection, and referral. In the community, primary health care related to sensory alterations is delivered in doctors' offices, homes, community centres, schools, and industry. Public health nurses, for example, conduct newborn hearing screenings during well-baby clinics and reinforce the importance of parents following the Canadian Ophthalmological Society eye examination guidelines. In ophthalmologists' offices, the ophthalmic nurse can reinforce health promoting practices and guide the patient to find appropriate resources, such as CNIB, to assist in living with visual impairment. In long-term care facilities, the nurse can use the Vision Screening Tool at admission to provide a baseline and then annually to assess for changes in vision. In school health programs, the nurse can stress the importance of maintaining the health of eyes and ears. Occupational health nurses play a key role in preventing injury, such as ensuring that safety standards are followed.

Nurses are often consulted for guidance when changes in vision and hearing occur. Consequently, your knowledge of screening techniques is important. It is also important that you are familiar with the normal aging process, as well as the signs and symptoms of common diseases so that appropriate suggestions for referral can be made.

nurse or public health nurse is usually responsible for vision testing. Their main role is one of detection and referral.

In Canada, glaucoma is the second leading cause of blindness and affects 250,000 Canadians (CNIB and Canadian Ophthalmological Society, 2009). It is important to recommend that patients between the ages of 40 and 64 years have an eye examination every two to four years. Examinations should occur every one to two years if the patient's family has a history of glaucoma or if the patient has had a serious eye injury in the past, is taking steroid medications, or is over 65 years of age (Smith & Neely, 2007).

Children at risk for hearing impairment include those with a family history of childhood hearing impairment, perinatal

► BOX 47-9

Recommended Vision Screening Guidelines for Infants, Children, and Youth

- Newborns to three months of age should have a complete examination of the skin and external eye structures, an inspection of the red reflex to assess for lenticular opacities or posterior eye disease. Abnormal exams should warrant an urgent referral to an ophthalmologist. Any newborns at risk for retinopathy of prematurity or family histories of hereditary ocular disease should be referred to an ophthalmologist.
- From 6 to 12 months of age, the above examinations should also be done, as well as assessments of ocular alignment, corneal light reflexes, and fixation and following.
- From three to five years of age, the above examinations should be done, as well as visual acuity testing with an age-appropriate tool.
- For children and youth aged 6 to 18, routine screenings and examinations with any visual complaints are indicated (Canadian Pediatric Society, 2009).

infection (rubella, herpes, cytomegalovirus), low birth weight, chronic ear infection, and Down syndrome. You should advise pregnant women of the importance of early prenatal care, avoidance of ototoxic drugs, and testing for syphilis or rubella.

Children with chronic middle ear infections, a common cause of impaired hearing, should receive periodic auditory testing. Parents must be warned of the risks (e.g., exposure to smoke, previous history of ear infections, siblings with otitis media, attending day care) and should seek medical care when the child has symptoms of earache or respiratory infection (Kerschner et al., 2005).

Many teenagers and young adults already have permanent hearing loss caused by exposure to excessive noise from such things as iPods, MP3 players, automobile stereo systems, and concerts. According to Vogel et al. (2008), MP3 players may be the most significant risk factor for music-induced hearing loss in adolescents, and they recommend laws be in place for sound limits for manufacturers of MP3 players. This hearing impairment results in loss of sound quality: sounds are barrel-like,

and consonants are hard to hear. Quintanilla-Dieck and colleagues (2009) found most people would be receptive to wearing hearing protection when around loud music if it was recommended by a health care provider. This represents an important area for health education, particularly with adolescents and young adults.

You should routinely teach parents and children to take precautions when involved in activities associated with high-intensity noise. As well, you should assess patients for noise exposure and participate in providing hearing conservation classes for teachers, students, and patients. Some “rules of thumb” are as follows: if someone standing a metre away has to shout to be understood, or if after the noise has stopped, the person experiences a temporary hearing loss or tinnitus, then the risk for hearing loss is increased. More seriously, if someone has to shout in a person’s ear to be understood, the person is at risk for permanent hearing loss if exposed to this level of noise for just five minutes per day (Health Canada, 2006).

The guidelines for hearing screening for adults are less prescriptive. In general, if a patient works or lives in an environment where the noise level is high, routine screening is highly recommended and may be mandated by occupational health and safety measures in the workplace. Nurses in occupational settings can assess for symptoms of tinnitus and make prompt referrals. Early detection may prevent hearing disabilities. Approximately 9000 Canadians experience some form of hearing impairment due to occupational exposure each year (Health Canada, 2010). Barnett (2007) recommends that, since aging is associated with degenerative changes, patients over 40 have a routine hearing assessment. Adults must not accept hearing loss as a natural part of aging. If a hearing loss does occur, it is important to have regular hearing testing. Nurses should encourage patients to follow through with recommendations for hearing aids.

Preventive Safety. Trauma is a common cause of blindness in children. Penetrating injuries from propulsive objects such as firecrackers, slingshots, rubber bands, or rocks and penetrating wounds from sticks, scissors, or toys are just a few examples. Parents and children require education about ways to avoid eye trauma. Safety equipment can easily be found in most sports shops and large department stores. In some Canadian jurisdictions, legislation or association bylaws mandate the wearing of protective equipment (e.g., visors in minor hockey) (CNIB, n.d., a).

Adults are at risk for eye injury while playing sports and working in jobs involving exposure to chemicals or flying objects. The Canadian Centre for Occupational Health and Safety has guidelines for safety in the workplace. Employers are required to have employees wear eye goggles or use equipment such as HPDs to reduce the risk of injury. Eyewash stations should be provided where a worker is exposed to potential contact with a biological or chemical substance (Canadian Centre for Occupational Health and Safety, 2010). Nurses in occupational health settings can reinforce use of protective devices and ensure that things such as eyewash stations are in close proximity to the risk for injury.

Preventing hearing loss requires individuals to avoid exposure to continuously high noise levels and brief, loud impulse noise. The potential for hearing loss increases as the decibel level rises. Various provincial jurisdictions mandate occupational noise exposure limits (*Alberta Occupational Health & Safety Act*, 2009). HPDs should be worn by patients who must

* BOX 47-10 RESEARCH HIGHLIGHT

Self-Reported Sensory Impairment and Life Satisfaction in Older French-Speaking Adults

Research Focus

Vision and hearing loss are known to have a negative impact on quality of life. There have been few studies that examined the relationship between sensory impairment and life satisfaction.

Research Abstract

The purpose of this study was to examine the contribution of sensory impairments to life satisfaction in the elderly. A secondary data analysis was conducted with 826 older French-speaking participants in a larger study. Hierarchical regression analysis was used to determine the role played by four sets of variables in life satisfaction: the demographic, health, lifestyle, and sensory impairment variables (vision and hearing). The final model explained 36% of the variance. The sensory impairment variables contributed significantly to the model. The findings indicate that vision and hearing are important components of life satisfaction.

Evidence-Informed Practice

- Determine if the individual has any aids.
- Determine whether they use these aids.
- Determine the last time they had their vision and hearing tested; did they follow through with the recommendations by the practitioner?
- Speak with a family member to convince the older adult to use the aids.
- Provide education on the use and care of the aids.
- Conduct vision and hearing screening regularly.

work around noise. Earplugs and earphones are useful in blocking high-decibel sounds (Box 47-10).

Another means of prevention involves regular immunization of children against diseases capable of causing hearing loss (e.g., rubella, mumps, and measles). Public health nurses, nurse practitioners, and nurses who work in physicians' offices, schools, and community clinics should reinforce the importance of early and timely immunization. When a child or an adult develops any type of health problem, caution should be used in prescribing drugs that are ototoxic.

Use of Assistive Devices. Health promotion requires appropriate use of assistive aids and good, routine hygiene measures. Patients who wear corrective contact lenses, eyeglasses, or hearing aids should make sure that they are kept clean, accessible, and functional (see Chapter 37). It is critical for contact lens wearers to frequently clean lenses and use the appropriate solutions for cleaning and disinfection. With the rise in the use of soft contact lenses, particularly extended-wear lenses, some patients have become casual with regard to both the care and the wearing time of the contacts; as a result, the number of serious corneal infections has increased. Infrequent lens disinfection, contamination of lens storage cases and contact lens solutions, and use of homemade saline add to a patient's risk.

► BOX 47-11

Troubleshooting Hearing Aid Malfunction**Objectives**

- Patient and family member will identify source of malfunction in hearing aid.
- Patient and family member will demonstrate hearing aid care.

Teaching Strategies

- Show patient and family member locations on hearing aid device where damage (e.g., cracks, fraying) is likely to occur: ear mould or case, earphone, dials, cord, and connection plugs.
- Demonstrate battery replacement and stress the importance of having an extra set of unused batteries available.
- Review method to check volume: turn dial to maximum gain and then check. Is voice clear?
- Consult manufacturer's directions for specific care measures for cleaning battery case and ear mould.
- Review factors to report to hearing aid laboratory: static, distortion of sound, poor volume quality.

Evaluation

- Ask patient and family member to describe types of common malfunctions with hearing aid.
- Ask patient and family to demonstrate battery removal and cleaning of the device.

Many people are reluctant to wear a hearing aid (Adams-Wendling & Pimple, 2008). Several factors may determine a person's likelihood for wearing a hearing aid: perceived need for improved hearing, attitude toward the hearing problem, and motivation to seek solutions. Cost may also be a concern for having hearing assessed and for purchasing a hearing aid if the patient is not covered by a provincial health plan. In some provinces, hearing aids must be purchased from an approved dispenser or dealer for the cost to be covered by the province's health program (Canadian Hard of Hearing Association, 2010).

Acknowledging a need to improve hearing is a person's first step. You can give patients useful information on the benefits of wearing a hearing aid. A wide variety of aids are available that may not only successfully enhance a person's hearing but can also be cosmetically acceptable. Chapter 37 summarizes the types of hearing aids available and tips for proper care and use. It is also important to have a significant other available to assist with hearing aid adjustment (Box 47-11).

If a patient has any of the following ear conditions, a hearing aid cannot be used: visible congenital or traumatic deformity of the ear, active drainage in the last 90 days, sudden or progressive hearing loss within the last 90 days, acute or chronic dizziness, unilateral sudden hearing loss within the last 90 days, visible cerumen accumulation or a foreign body in the ear canal, pain or discomfort in the ear, or an audiometric air-bone gap of 15 decibels or greater. All but the last of these can be detected on physical examination. Referrals to or recommendations that the patient see an otolaryngologist or audiologist for further counselling should be made (Ebersole et al., 2007).

Another option for those with severe to profound hearing loss is a cochlear implant. This is a small, complex electronic device that can help provide a sense of sound to a person who is profoundly deaf or severely hard of hearing. The implant

consists of an external portion that sits behind the ear and a second portion that is surgically placed under the skin. An implant does not restore normal hearing. Instead, it can give a deaf person a useful representation of sounds in the environment and help him or her understand speech.

Promoting Meaningful Stimulation. Life becomes more enriching and satisfying when meaningful and pleasant stimuli exist within a person's environment. You can help patients make adjustments to their environment in many ways so that it becomes more stimulating. To do this, consider the normal physiological changes that accompany sensory deficits.

Vision. As a result of the normal changes of aging, the pupil's ability to adjust to light diminishes. As a result, older adults are often more sensitive to glare. You can suggest ways for the patient to minimize glare by selecting satin and non-gloss finishes for walls and countertops in the home, selecting a tile pattern for flooring, and choosing sheer curtains, tinted windows, or adjustable shades to reduce outdoor light. Wearing sunglasses outside can reduce the glare of direct sunlight.

The ability to read is important to everyone. Therefore, patients should be encouraged to use their glasses whenever possible (e.g., during procedures and patient instruction), which helps patients remain oriented, maintain some control, and retain their dignity. Patients with reduced visual acuity may need more than corrective lenses. A pocket magnifier can help a patient read most printed material. Telescopic lens eyeglasses are smaller, are easier to focus, and have a greater range. Books and other publications are also available in larger print. If a patient has a legal or other important document he or she wishes to read, standard copying machines have enlarging capabilities. Closed-circuit television magnifying units or portable or desktop video magnifiers using solid-state digital technology enlarge written characters. Minimum and maximum magnification varies from 12 to 60 times the original, depending on the screen size. As well, many word processing programs allow print to be enlarged. Audio-recorded books are available and can be readily purchased in bookstores or borrowed from public libraries or CNIB.

With aging, a person experiences a change in colour perception. You can offer suggestions of ways the patient may decorate a room and paint hallways or stairwells so that differentiations can be made in surfaces and objects in a room.

Hearing. To maximize residual hearing function, you work closely with the patient to suggest ways to modify the environment. Telephones and televisions can be amplified. Alarm clocks that shake the bed or activate a flashing light are useful devices. An innovative way to enrich the lives of those with a hearing impairment is recorded music. Some patients with severe hearing loss can hear music recorded in the low-frequency sound cycles. Closed captioning, in which audio content and nonspeech information, such as the identity of speakers and sound effects, are described using words or symbols, is available for many television programs.

One way to help an individual with a hearing loss is to ensure that the problem is not impacted cerumen. Removal of cerumen by irrigation (see Chapter 37) can significantly improve not only the patient's hearing ability but also the patient's mental status (Armstrong, 2009).

Taste and Smell. You can easily promote the sense of taste by using measures to enhance remaining taste perception. Good oral hygiene keeps the taste buds well hydrated. Taste

perception is heightened if foods are well seasoned, differently textured, and eaten separately. Flavoured vinegar or lemon juice can add tartness to food. Ask the patient what foods appeal most to taste. If taste perception is improved, food intake and appetite will also improve.

Stimulation of the sense of smell with aromas such as brewing coffee, cooking garlic, and baking bread can heighten taste sensation. Avoid blending or mixing foods because these actions make it difficult to identify tastes. Older adults should chew food thoroughly to allow more food to contact the remaining taste buds.

Smell can be improved by strengthening pleasant olfactory stimulation. A patient's environment can be made more pleasant with smells such as cologne, mild room deodorizers, fragrant flowers, and sachets, although you must assess the patient for allergies or sensitivities before using these items. Certain aromas may actually cause patients to lose their appetites.

Removal of unpleasant odours improves the quality of a person's environment. You should keep a patient's room clean, empty bedpans or urinals after use, remove and dispose of soiled dressings, and keep bathroom doors closed.

Touch. Patients with reduced tactile sensation usually have the impairment over a limited portion of their bodies. You can stimulate existing function by using touch therapeutically. If the patient is willing to be touched, hair brushing, a back rub, and touching of the arms or shoulders are ways of increasing tactile contact. When sensation is reduced, firm pressure may be necessary for the patient to feel your hand. Turning and repositioning can also improve the quality of tactile sensation. When invasive procedures are being performed, it is important to use touch by holding the patient's hands and keeping them warm and dry.

If a patient is overly sensitive to tactile stimuli (**hyperesthesia**), you must minimize irritating stimuli. Keeping bed linens loose to minimize direct contact with the patient and protecting the skin from exposure to irritants are helpful measures. If the patient has numbness and tingling or pain in the hands, as with carpal tunnel syndrome, special wrist splints may be worn to dorsiflex the wrist to relieve the nerve pressure. For those patients who use computers, special keyboards and wrist pads are available to decrease the pressure on the median nerve, aid in relief of pain, and promote healing.

Establishing Safe Environments. When sensory function becomes impaired, individuals become less secure and the world around them becomes smaller. Older adults in particular find it important to feel secure about their immediate environment. Feeling safe allows a person to function within the home and helps provide a sense of independence. You can suggest various strategies to assist patients in making their living environment safer without restricting their independence. During a home visit or while completing an examination in the clinic, suggestions for home safety can be discussed. The nature of the actual or potential sensory loss determines the safety precautions taken.

Adaptations for Visual Loss. When a patient experiences a decrease in visual acuity, peripheral vision, adaptation to the dark, and depth perception, safety becomes a concern. With reduced peripheral vision, a patient cannot see panoramically because the outer visual field is less discrete. This creates a special hazard for driving or walking in crowded areas. Adults with reduced adaptation to the dark require three times as much light to see objects as they did as young adults. With

reduced depth perception, a person cannot see how far away objects are located, making walking down stairs or over uneven surfaces dangerous.

safety alert To create a safe environment, the nurse begins by looking at the results of the home environment assessment (see Chapter 36).

Driving can also be a safety hazard. Reduced peripheral vision may prevent a driver from seeing a car in an adjacent lane. Reduced adaptation to the dark and sensitivity to glare make driving at night a significant risk. Although vision is a primary consideration for safety, other factors exist as well. In the case of older adults, decreased reaction time, reduced hearing, and decreased strength in the legs and arms may further compromise driving skills. Safety tips for those who continue to drive include driving in familiar areas, not driving during rush hour, avoiding major highways for local drives, using rear-view and side-view mirrors when changing lanes, avoiding driving at dusk or at night, keeping the car in good working condition, and carrying a cellular phone (but not using it while driving). Older drivers with visual impairment are 40% more likely to have caused a collision than those without visual impairment. Auto collisions are the number one cause of accidental death in 65- to 74-year-olds (Government of Alberta Transportation, n.d.).

In Ontario, drivers over the age of 80 are required to renew their licenses every two years. The renewal process involves a vision test, a written test, a group educational session, and a driving test for some applicants (Ontario Ministry of Transportation, n.d.). British Columbia requires a driver's retest for individuals approaching their 80th birthdays. Drivers need to complete a medical examination, vision test, and road test (BCAA Traffic Safety Foundation Mature Drivers Program, n.d.).

Visual alterations can make conducting normal activities of daily living more difficult. Because of reduced depth perception, patients can trip on throw rugs, runners, or the edge of stairs. Flooring or carpeting should be kept in good repair. Advise the patient to use low-pile carpeting. Thresholds between rooms should be level with the floor. Clutter should be removed to ensure clear pathways for walking. Furniture should be arranged so that the patient can move about easily without fear of tripping or running into objects. Any stairwell should have a securely fastened handrail extending the full length of the stairs.

Front and back entrances to homes, work areas, and stairwells need to be properly lit. Light fixtures need higher-wattage bulbs with wider illumination. Although less energy efficient, incandescent lighting may be preferred over fluorescent lighting because of the flickering of fluorescent lights. The CNIB Web site offers suggestions for lighting and other modifications for the visually impaired. A light switch should be located at the top and bottom of stairwells. It is also important that lighting on the stairs does not cast shadows. You should ensure that the patient is able to see the edge of each step clearly, especially the first and last steps. When possible, steps inside and outside the home should be replaced with ramps.

When a patient is unable to see visual contrasts, a number of interventions can be helpful. Sometimes settings on electrical appliances and equipment are only highlighted in black and white or shades of grey. Coloured tape, paint, nail polish,

or raised label dots can be used to colour-code appliance dials. Colour can also be useful to highlight the edge of stairs. Applying a broad strip of coloured tape at the stair edge can help a person better see the edges. Tour the home with the patient to find opportunities for colour-coding. Telephones with large numbers may be helpful.

You can also ensure that the patient is able to self-administer medications safely. Labels on medication containers should be in large print. A friend or spouse should always be familiar with dosage schedules. Using a magnifying glass or having family members read prescription medication labels for the patient may be helpful. Audible prescription labelling may become more common in the future (McMahon & Curtis, 2009). People who are visually impaired may have some difficulty manipulating eyedroppers. Eye-drop dispensers are available and often allow older or people with vision loss to independently administer their drops.

Adaptations for Reduced Hearing. Important environmental sounds may best be heard if amplified or changed to a lower-pitched, buzzer-like sound. Lamps are available that respond with light to sounds such as doorbells, burglar alarms, smoke detectors, and babies crying. These lamps can be purchased from hearing aid dealers, telephone companies, and appliance stores. Signalling devices allow the person with hearing loss greater independence. Family members or anyone who calls the patient regularly should learn to let the telephone ring for longer periods. Amplified receivers for telephones and telephone communications devices use a computer and a printer to transfer words over the telephone for people who are hearing impaired. Both sender and receiver must have the special device to complete a call. Telecommunication relay services (TRS) are available from most telephone companies. A telephone operator service translates voice to text and vice versa. Video relay services (VRS) are also available. VRS enables individuals with hearing disabilities who use American Sign Language to communicate with voice telephone users through video equipment rather than through typed text. Video equipment links the VRS user with an operator so that they can see and communicate with each other in signed conversation (Federal Communications Commission, 2010). The Canadian Hard of Hearing Association (2009) document entitled *Keys to the Communication Revolution* provides a list of key technological breakthroughs for the hearing impaired; however, some of these technologies are not readily available in Canada at this time.

Adaptations for Reduced Olfaction. A reduced sensitivity to odours means that the patient may be unable to smell leaking gas, a smouldering cigarette or fire, or spoiled food. The patient should use smoke and carbon monoxide detectors and other alternative precautions, such as checking ashtrays or placing cigarette butts in water. A patient can learn to check dates on food packages and the colour and texture of food. Leftovers should be kept in labelled containers with the preparation date. Pilot gas flames should be checked visually or professionally on a regular basis (Griggs, 2008).

Adaptations for Reduced Tactile Sensation. When patients have reduced sensation in their extremities, they are at risk for injury from exposure to temperature extremes. You should caution them on the use of water bottles or heating pads (see Chapter 46). The temperature of bathwater should be checked routinely before stepping into the tub. The temperature setting on the home water heater should be no higher than 48.8°C. Current Canadian regulations allow domestic

► BOX 47-12

Communication Methods for Patients Who Have a Hearing Impairment

- Get the patient's attention. Do not startle the patient when entering the room. Do not approach a patient from behind. Be sure the patient knows you wish to speak.
- Face the patient and stand or sit on the same level. Be sure your face and lips are illuminated to promote lip-reading. Keep hands away from the mouth.
- If the patient wears glasses, be sure they are clean so that your gestures and face can be seen.
- If the patient wears a hearing aid, make sure it is in place and working.
- Speak slowly and articulate clearly. Older adults may take longer to process verbal messages.
- Use a normal tone of voice and inflections of speech. Do not speak with something in your mouth.
- When you are not understood, rephrase rather than repeat the conversation.
- Use visible expressions. Speak with your hands, your face, and your eyes.
- Do not shout. Loud sounds are usually higher pitched and may impede hearing by accentuating vowel sounds and concealing consonants. If it is necessary to raise your voice, speak in lower tones.
- Speak toward the patient's best or unaffected ear. Use written information to enhance the spoken word.
- Do not restrict a deaf patient's hands. Ensure that IV lines are not secured to both of the patient's hands if the preferred method of communication is sign language.
- Avoid speaking from another room or while walking away.
- Make a note at the nursing station that the patient has a hearing impairment or is deaf.

water heaters to be factory set at 60°C. Researchers from the University of Toronto studied the cost-effectiveness of a proposed public health legislative and educational strategy to reduce scald injuries caused by tap water. The researchers concluded that legislation for lower thermostat settings on water heaters and annual educational notices for utility customers would decrease morbidity from tap water scalds and would also be cost effective (Han et al., 2007).

Promoting Communication. A sensory deficit can cause a person to feel isolated because of an inability to communicate with others. It is important for individuals to be able to interact with people whom they encounter. The nature of the sensory loss influences the methods and styles of communication that you can use (Box 47-12). Communication methods can also be taught to family members and significant others (see Chapter 17).

When beginning a conversation with a patient who has a hearing deficit, it helps to reduce any background noise by turning off or lowering the volume of any television, appliance, or radio. It is also helpful to have conversations in settings where the acoustics are better, which aids in controlling and muffling extraneous background noises. In a group setting, forming a semicircle in front of the patient helps him or her see who is speaking next, thereby fostering group involvement. The patient with a hearing impairment may be able to

speak normally. However, the deaf patient's inability to hear self-spoken words may cause serious speech alterations. Patients may use sign language (American or Quebec Sign Language), lip-read, write with a pad and pencil, or learn to use a computer for communication. Special communication boards that contain common terms used in nursing care (e.g., pain, bathroom, dizzy, or walk) help patients express their needs.

Patient instruction is one aspect of communication. Teaching booklets are available in large print. The patient who is blind may require more frequent and detailed verbal descriptions of information. This is particularly true if no instructional booklets are written in Braille. Patients can learn by listening to audiotapes or the sound portion of a televised teaching session. Patients with hearing impairment may benefit from written instructional materials and visual teaching aids (e.g., posters and graphs). Demonstrations are very useful. Also, owing to a 1997 Supreme Court ruling, provinces must now pay for sign language interpreters for deaf patients when they receive medical treatment.

Acute Care

When patients enter acute care settings for therapeutic management of sensory deficits or as a result of traumatic injury, you should try to maximize sensory function existing at the time. Safety is an obvious priority until sensory status is either stabilized or improved. For example, patients with sensory deficits have a high risk for falls in the acute care environment. It also becomes very important to know the extent of any existing sensory impairment before the acute episode of illness so that you can reinforce what the patient already knows about self-care or plan for more instruction before and following discharge.

Patients who are acutely ill are also at risk for developing sensory alterations. Your main challenge becomes introducing regular, meaningful stimulation so that patients maintain a clearer perception of their immediate environment. Ongoing explanations help orient the patient to any new stimuli within their environment and reduce fear and disorientation.

Orientation to the Environment. The patient with recent sensory impairment requires a complete orientation to the immediate environment. Reorientation to the institutional environment may be provided by ensuring that name tags on uniforms are visible, addressing the patient by name, explaining where the patient is (especially if patients are transported to different areas for treatment), and using conversational cues to time or location. Reduce the tendency for patients to become confused by offering short, simple, repeated explanations and reassurance. Family members and visitors can also help orient patients to the hospital surroundings.

Patients with serious visual impairment must feel comfortable in knowing the boundaries of the immediate environment. They may want to touch the boundaries of a room or objects to gain a sense of their surroundings. The patient may need to walk through a room and feel the walls to establish a sense of direction. You can help by describing furniture or equipment within the room. As it takes time to absorb a room's arrangement, the patient may need further reorientation, with the nurse explaining the location of key items (e.g., call light, telephone, and chair).

It is important to keep all objects in the same position and place. Simply moving a chair aside may create a dangerous safety hazard. Ensure that you ask the patient if any

item should be arranged to make ambulation easier. Traffic patterns should be kept clear, and use of furniture with sharp edges should be avoided. The patient who is blind needs extra time to perform tasks and a detailed description of how to perform an activity.

Patients confined to bed are at risk for sensory deprivation. Normally, movement gives an integrated awareness of the self through vestibular and tactile stimulation. A person's sensory perception is influenced by movement patterns. The limited movement of bedrest changes how a person interprets the environment; surroundings seem different, and objects seem to assume shapes different from normal. A person who is on bedrest requires routine stimulation through range-of-motion exercises, positioning, and participation in self-care activities (as appropriate). Comfort measures such as washing the patient's face and hands and providing back rubs can help improve the quality of stimulation and lessen the chance of sensory deprivation. Planning time to talk with patients is also essential. Explain unfamiliar environmental noises and sensations. As well, a calm, unhurried approach during contact with a patient gives you quality time to help reorient and familiarize the patient with care activities. The patient who is well enough to read will benefit from a variety of reading materials.

Controlling Sensory Stimuli. Excessive stimuli for patients at risk for sensory overload should be controlled. You can reduce sensory overload by organizing the care plan. Combining activities such as dressing changes, bathing, and vital sign measurement in one visit prevents the patient from becoming overly fatigued. Coordination with laboratory and radiology departments may help minimize the number of procedures the patient must undergo. Encourage, as appropriate, a family member to sit quietly with a patient or involve the patient in an undemanding, repetitive activity, such as combing hair. The patient also needs scheduled time for rest and quiet. Planning for rest periods often requires cooperation from family, visitors, and health care colleagues. Many nursing care units have instituted a set time for rest periods.

When patients experience sensory overload or deprivation, the resultant behaviour can be difficult for family or friends to accept. Encourage the family not to argue with or contradict the confused patient but to explain calmly the patient's location and identity and the time of day. Engaging the patient in a normal discussion about familiar topics may assist in reorientation. Prearranging tests and procedures with departments reduces the amount of time needed for tests and examinations. Anticipating patient needs, such as voiding, helps reduce uncomfortable stimuli.

You can also try to control extraneous noise in and around the patient's room. It may be necessary to ask a roommate to lower the volume on a television or to move the patient to a quieter room. Equipment noise should be kept to a minimum. Bedside equipment not in use, such as suction and oxygen equipment, should be turned off. You also should try to avoid abrupt loud noises, such as suddenly causing the overbed table to adjust to the lowest level. Nursing staff should also try to control laughter or conversation at the nurses' station. Nurses should allow patients to close room doors (Robinson et al., 2008).

When the patient leaves an acute care setting for home, you should communicate with colleagues in the home care setting about the interventions that helped the patient adapt to sensory problems. Similarly, information describing the patient's existing sensory deficits should be reported. Continuity of care is

achieved when the patient is required to make only minimal changes to the plan of care in the home setting.

Safety Measures. The patient with recent visual impairment often requires help with walking. The presence of an eye patch, frequently instilled eye drops, and the swelling of eyelid structures following surgery are just a few factors that cause a patient to need more assistance than usual. A sighted guide can give confidence to the visually impaired person and ensure safe mobility. The CNIB has published a manual for assisting someone with vision loss (CNIB, n.d., c). Touhy et al. (2012) list four suggestions for a sighted guide:

- Ask the patient if he or she wants a “sighted guide.”
- If assistance is accepted, offer an elbow or arm. Instruct the patient to grasp your arm just above the elbow. If necessary, physically assist the person by guiding his or her hand to your arm or elbow.
- Go one half-step ahead and slightly to the side of the person. The shoulder of the person should be directly behind your shoulder. If the person is frail, place his or her hand on your forearm.
- Relax and walk at a comfortable pace. Warn the patient when you approach doorways or narrow spaces.

While walking the patient, describe the course of movement and ensure that obstacles have been removed. A patient with visual impairment should never be left standing alone in an unfamiliar area. For patients who undergo eye surgery, it is important to teach family members techniques for assisting with ambulation. For those patients who are blind, mobility training is available from CNIB. Guide dogs may also prove useful (CNIB, n.d., b). A patient who spends considerable time in bed should have a call light nearby. Necessary objects should be placed in front of the patient to prevent falls caused by reaching over the bedside. Side rails may also be useful to provide added security. At night, a night light reduces the time required for the eyes to adapt to the dark and allows the patient to see well enough to function without keeping the regular light on.

Face the patient when speaking, use simple sentences, and speak more slowly and at a normal volume. It is wise to note on the intercom button and the patient’s chart if the patient is deaf or blind. A patient lacking the ability to speak cannot call out for assistance. Patients should have message boards or the call light easily available.

Patients with reduced tactile sensation risk injury when their conditions confine them to bed because they are unable to sense pressure on bony prominences or the need to change position. These patients rely on nurses for timely repositioning, moving tubes or devices they may be lying on, and turning them to avoid skin breakdown. When the patient is less able to sense temperature variations, you should be extra cautious when applying heat and cold therapies and preparing bathwater. You must check the condition of the patient’s skin frequently.

A commonly used skin assessment tool is the Braden Scale (see Chapter 46, p. 1260) (Braden & Bergstrom, 1988), for assessing pressure ulcer risk for patients in acute or long-term care as well as homes and community settings. One component of the Braden Scale is sensory impairment. Canadian recommendations include assessing all acute care admissions for pressure ulcer risk and at 48-hour intervals thereafter (every shift for high-risk patients); assessing long-term care patients on admission and every 48 hours for the first week; educating family members and caregivers about skin

assessments and care for patients in the community (RNAO, 2005; Stevenson, 2009).

Restorative and Continuing Care

Maintaining Healthy Lifestyles. After a patient has experienced a sensory loss, it becomes important to understand the implications of the loss and to make the adjustments needed to continue a normal lifestyle. Sensory impairments need not prevent a person from leading an active, rewarding life. Many of the interventions applicable to health promotion, such as adapting the home environment, can be used after a patient leaves an acute care setting.

Understanding Sensory Loss. Patients who have experienced a recent loss must understand how to adapt so that their living environments can be safe and appropriately stimulating. Family members should understand how a patient’s sensory impairment affects normal daily activities. Family and friends can be more supportive when they understand sensory deficits and the types of elements that worsen or lessen sensory problems. Resources are available within a community that provide information that assists patients with personal management needs. For example, CNIB, the Canadian Hearing Society, and the Canadian Association of the Deaf offer resource materials and product information.

Socialization. The ability to communicate is gratifying. It tests our intellect, opens opportunities, and allows us to exchange the feelings we have about others. When interactions are hindered by sensory alterations, a person can feel ineffective and lose self-esteem.

Interacting with others can become a burden for many patients with sensory alterations. Asking people to continually repeat what they say is both embarrassing and exhausting for a patient with hearing loss. Many patients lose the motivation to engage in social situations. As a person withdraws from interaction, a deep sense of loneliness can develop. You can introduce therapies to reduce loneliness, particularly for older patients (Box 47-13). In addition, family members need to learn to focus on a person’s ability rather than on the disability. It should not be assumed, for example, that a person who is hard of hearing does not wish to speak. A person who is blind can still enjoy a walk through a park with a companion describing the sights around them.

* BOX 47-13 FOCUS ON OLDER ADULTS

Interaction Strategies With a Focus on Older Adults

- Spend time with a person, either in silence or in conversation.
- Use physical contact—holding a hand, embracing a shoulder—to convey caring.
- Recommend alterations in living arrangements if physical isolation is a factor.
- Assist older adults to maintain contact with people important to them.
- Help obtain information about mutual help groups.
- Arrange for security escort services as needed.
- Suggest that the patient obtain a pet that is easy to care for.
- Link the patient with religious or other organizations attuned to the social needs of older adults.

Promoting Self-Care. The ability to perform self-care is essential for self-esteem. People with chronic conditions who are supported to perform self-care report a higher quality of life, independence, and self-esteem, along with lower levels of depression, anxiety, and fatigue (Robinson, 2010). Frequently, family members and nurses believe that patients with sensory impairments require assistance when, in fact, they can help themselves. Useful guidelines are available to assist patients with visual or tactile impairment so that they can help themselves with daily living activities. For example, a meal tray can be set up as though food on the tray and condiments and drinks around the tray are numbers on the face of a clock (Figure 47-5). The visually impaired patient can easily become oriented to the items after the nurse or family member explains each item's location.

The patient with visual problems may need assistance in reaching toilet facilities safely. Safety bars should be installed near the toilet. It may be helpful to have the bar a different colour than the wall for easier visibility. Towels should never be placed on safety bars because they may interfere with a person's grasp. Toilet paper should be within easy reach. The use of sharply contrasting colours, especially red, on drawers and other places helps promote functional independence. Choosing clothes that match can be an issue, but techniques such as hanging clothes together on a hanger or marking them with similar labels often overcome this difficulty. The patient's preference must always be considered when helping to arrange or buy clothes.

If tactile sense is diminished, the patient can dress more easily with zippers or Velcro strips, pullover sweaters or blouses, and elasticized waists. If a patient has partial paralysis and reduced sensation, the affected side should be dressed first.

Patients with proprioceptive problems may lose balance easily. Floor mats should have rubberized, skid-proof bottoms. They should be checked and replaced as needed. Bathrooms should have nonskid surfaces in the tub and shower. Grab bars should be installed either vertically or horizontally in tubs and showers, depending on how the patient is able to grasp or hold

Figure 47-5 Location of food using the clock as a frame of reference.

on to the bar. You can instruct family members to supervise ambulation and sitting, make frequent checks to prevent falls, and help caution the patient against leaning forward.

Any sensory impairment has a significant influence on body image, and it is important for the patient to feel well groomed and attractive. Some patients may need assistance with basic grooming. Others may need assistance with medication selection, clothing identification, and learning to manage routine procedures, such as blood pressure and glucose monitoring. A variety of aids are available to help individuals with varying types of sensory deficits. It is important to assist patients in maintaining a degree of independence and in having as much control over the management of their care and lifestyle as possible.

❖Evaluation

Patient Care

It is essential to determine whether care measures maintain or improve patients' ability to interact and function within their environment. Only patients themselves will know if their sensory abilities are improved and which interventions or therapies are the most successful (Figure 47-6). To evaluate the

Figure 47-6 Critical thinking model for sensory alterations evaluation.

effectiveness of nursing interventions, you will use critical thinking and make comparisons with the baseline sensory assessment data to evaluate if sensory alterations have changed.

As the nurse, you determine if expected outcomes have been met. The nature of the sensory alteration influences the way you evaluate the outcome of care. Look back on the goals and interventions for nursing care. Discuss goals and interventions with the patient, family, and multidisciplinary team members and reflect on their perspectives of meeting these goals. What went well? What could have been improved? What still needs to be done? What is the patient's perception of the nursing care? For example, you use proper communication techniques with a patient with a hearing deficit and then evaluate whether the patient has gained the ability to hear or interact more effectively. When expected outcomes have not been achieved, it may be necessary to change interventions or alter the patient's environment. Family members may need to be involved in support of the patient. You may also consult with the multidisciplinary team (e.g., physician, occupational therapist, audiologist) for suggestions to achieve unmet needs. The patient must be involved in all evaluation and planning activities.

If nursing care has been directed at improving sensory acuity, evaluate the integrity of the sensory organs and the patient's ability to perceive stimuli. Any interventions designed to relieve problems associated with sensory alterations are evaluated on the basis of the patient's ability to function normally without injury. When you attempt to directly or indirectly (through education) alter the patient's environment, evaluation is directed at observing whether the patient makes environmental changes. When patient teaching is designed to improve a patient's sensory function, it is important to determine whether the patient is following recommended therapies. Asking the patient to explain or demonstrate self-care skills evaluates the level of learning that has occurred. It may be necessary to reinforce previous instruction if learning has not taken place.

Patient Expectations

If you have successfully developed a good relationship with a patient and have a therapeutic plan of care, subtle behaviours often indicate the level of the patient's satisfaction. Note whether the patient responds appropriately, such as by smiling. As well, observe whether the patient interacts more and is not asking to have information repeated. Ask the patient, "Can you tell me if you feel we have done all we can do to help improve your ability to hear?" If the patient's expectations have not been met, then you need to spend more time understanding the patient's needs and specific preferences. Ask the patient, "What else can the health care team do to meet your needs?" Working closely with the patient and family will enable you to redefine expectations that can be realistically met within the limits of the patient's condition and therapies. Interventions are effective when goals and expectations have been met.

❖ KEY CONCEPTS

- When sensory function is impaired, the sense of self is impaired and can affect one's ability to socialize.
- Uncorrected vision impairment can lead to falls, fractures, depression, social isolation, behavioural changes, and cognitive impairment.

- Sensory deprivation results from an inadequate quality or quantity of sensory stimuli.
- Aging usually results in a gradual decline of acuity in all senses.
- Do not confuse medical conditions or disease symptoms with normal aging changes.
- Patients who are older, immobilized, or confined in isolated environments are at risk for sensory alterations.
- Assessment of a patient's health promotion habits helps reveal risks for sensory impairment.
- An individual may not admit to a sensory loss.
- An assessment of hazards in the environment requires the nurse to tour living areas in the home and to look for conditions that increase the chances of accidents.
- The plan of care for patients with sensory alterations needs to include participation by family members.
- The plan of care may differ if the sensory alteration is chronic or short term in nature.
- Care of patients at risk for sensory deprivation includes introducing meaningful and pleasant stimuli for all senses.
- To prevent sensory overload, the nurse controls stimuli and orients the patient to the environment.

❖ CRITICAL THINKING EXERCISES

1. Mr. Tully is a 54-year-old farmer who is having a physical examination. Overall, his health is good. His wife reports that over the past year, he has lost interest in being involved in social gatherings, is more irritable, and often has asked her to repeat what was said. Recently, he has complained of a constant buzzing in his ears. What assessment data are needed? What specific interventions may be needed?
2. Mrs. Marfell, 79 years old, is visiting the outpatient cardiac centre for a routine checkup. You notice that she needed help reading the physical forms. She also told you she is having increased difficulty driving at night. What additional assessment data should you gather from Mrs. Marfell?
3. You have an opportunity to speak with a group of parents and students regarding the importance of hearing protection. What information would you share with this varied age group to promote healthy hearing?

❖ REVIEW QUESTIONS

1. The following sense enables a person to be aware of the position and movement of body parts without seeing them:
 1. Auditory
 2. Kinesthetic
 3. Tactile
 4. Gustatory
2. A sense that allows a person to recognize an object's size, shape, and texture is
 1. Stereognostic
 2. Kinesthetic
 3. Tactile
 4. Gustatory
3. A patient who is in constant pain and undergoes frequent monitoring of vital signs is at risk for experiencing sensory
 1. Deprivation
 2. Deficits
 3. Overload
 4. Stimuli

4. Proprioceptive changes after 60 years of age include increased
 1. Hearing and vision impairment
 2. Difficulty with balance, spatial orientation, and coordination
 3. Hearing impairment and difficulty with balance and coordination
 4. Vision impairment and difficulty with spatial orientation
5. For a patient who has a hearing impairment, the nurse should
 1. Approach a patient quietly from behind
 2. Face the patient when speaking and use a louder-than-normal tone of voice
 3. Select a public area to have a spoken conversation
 4. Face the patient when speaking and speak slower and at a normal volume
6. When obtaining a history of the patient's hearing loss, the nurse should ask,
 1. "How long have you been deaf?"
 2. "Do you also have vision problems?"
 3. "Why don't you pay attention to me while I speak?"
 4. "How does your hearing now compare with your hearing a year ago?"
7. A realistic goal for an older adult patient who drives is to
 1. Drive very slowly all of the time
 2. Use rear-view and side-view mirrors when changing lanes
 3. Always drive at night to prevent sun glare
 4. Drive during rush hour when others are on the road
8. To prevent hearing impairment among children, a nursing intervention is to teach parents, schoolteachers, and children to
 1. Avoid activities in which crowds and loud noises occur
 2. Delay childhood immunizations until hearing can be verified
 3. Take precautions when involved in activities associated with high-intensity noises
 4. Administer antibiotics to reduce the risk of infections
9. A high priority in a home assessment for a patient with diminished olfaction is the inclusion of
 1. A low-temperature water setting
 2. Extra lighting in hallways
 3. Smoke detectors on all levels
 4. Amplified telephone receivers
10. Sensory deficits happen when a problem with sensory reception or perception occurs. As a result, patients may
 1. Withdraw socially to cope with the loss
 2. Rely solely on one sense
 3. Respond normally to stimuli
 4. Function safely within their environment

Care of Surgical Patients

Original chapter by Carrie Sona, RN, MSN, CCRN, ACNS, CCNS

Canadian content written by Frances Fothergill-Bourbonnais, RN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Understand the aspects of perioperative nursing care.
- Differentiate between classifications of surgery and types of anaesthesia.
- List factors to include in the preoperative, intraoperative, and postoperative assessment of a surgical patient.
- Demonstrate postoperative exercises: diaphragmatic breathing, coughing, turning, and leg exercises.
- Design a preoperative teaching plan.
- Prepare a patient for surgery.
- Explain the nurse's role in the operating room.
- Describe the rationales for nursing interventions designed to prevent postoperative complications.
- Explain the differences and similarities in caring for ambulatory (day) surgical patients versus inpatient surgical patients.

Perioperative nursing care includes care given before (preoperative), during (intraoperative), and after (postoperative) surgery. Surgical procedures generally take place in a hospital, although some minor surgical procedures can be conducted in a physician's office. Perioperative nursing is based on your understanding of several important principles, including the following:

- Excellence in perioperative practice
- Interprofessional teamwork
- Effective and therapeutic communication and collaboration with the patient, the patient's family, and the surgical team
- Effective and efficient patient assessment and intervention in all phases
- Advocacy on behalf of the patient and the patient's family
- Understanding of cost containment
- Understanding of patient safety

You must practise surgical asepsis, thoroughly document care, and emphasize patient safety in all phases of care. The nursing process provides a basis for perioperative nursing, with you individualizing strategies so that the patient receives continuity of care from admission into the health care system through convalescence. By using the nursing process, you can help to anticipate needs and minimize complications. The World Health Organization has produced the Surgical Safety Checklist (WHO, 2008) to facilitate patient safety throughout the operative procedure.

The continuing care of the surgical patient has shifted from hospital-based convalescence to home-based convalescence, with the patient and family assuming increased responsibility. As the length of hospital stays decreases, the educational needs of the patients and their families increase. Patients are sent home often with complex medical or surgical conditions that require education and follow-up. Effective teaching and early discharge planning are essential to ensure positive surgical outcomes (Suhonen & Leino-Kilpi, 2006).

History of Surgical Nursing

Surgery gave physicians the means to treat conditions that were difficult or impossible to manage solely through medicinal applications. Early surgeons had little knowledge of the principles of asepsis, and anaesthesia techniques were primitive and unsafe. Indeed, the early surgeon's success was based on speed. The discovery of anaesthesia in the 1840s revolutionized surgery. Anaesthesia provided a combination of analgesia, muscle relaxation, and amnesia, which allowed the time for surgical procedure to be extended. The value of handwashing and the development of germ theory in the 1860s (Pasteur) and 1870s (Koch) triggered the study of aseptic technique, which reduced postoperative infections and mortality. Joseph Lister (1827–1912) was associated with antiseptics or listerism. Initially, antiseptics was one way to protect patients from pathogens in the environment. After experimenting with carbolic acid dressings and continuous carbolic acid sprays during surgical operations, in 1867 Lister described a reduced incidence of gangrene and mortality. He eventually abandoned carbolic acid by 1890, when Koch demonstrated heat to be more effective than chemicals for sterilizing instruments (Porter, 1997). Therefore, Pasteur, Lister, and Koch helped provide a scientific basis to prevent infection in hospitals.

Asepsis and the techniques associated with it ensured that the patient did not acquire in-hospital infections. Germ theory influenced nursing practice through the creation of carefully delineated procedures designed to preserve asepsis (McPherson, 1996). Nurses working in the first operating rooms (ORs) cleaned the rooms and equipment, prepared the solutions and dressings, performed technical tasks such as obtaining supplies, administered anaesthetics as graduates, and occasionally accompanied patients to the surgical ward to deliver nursing care.

In Canada, OR nursing began to be part of training at Montreal General Hospital in 1890 ("Nurses life in the Montreal General Hospital," 1892). Toronto General Hospital, St. Michael's Hospital in Toronto, and Winnipeg General Hospital quickly followed suit. OR nursing in the early twentieth century became organized around the technology of surgery. Nurses ensured that the aseptic conditions of the surgical environment were maintained by all personnel and, along with physicians, became the first specialists in anaesthesia.

As sterile ORs developed, OR nursing became a specialty separate from anaesthesia and surgical nursing. Two roles emerged: the sterile scrub nurse, who handled the instruments and passed them to the surgeon, and the circulating nurse, who ensured that all sponges used in operations were accounted for outside the patient's body and that aseptic conditions were maintained. OR nursing was confined to activities in and around the OR and was a well-established field of practice by the 1920s.

During the Second World War, a proliferation of courses that focused on OR nursing developed. These postdiploma courses subsequently enabled nurses to join the military, where they were highly valued to work with trauma patients (Toman et al., 2006). During the Second World War, the expertise of nurses in caring for soldiers with traumatic injuries accelerated. "The primary purpose of dressings shifted from one of limiting blood loss in the field to one of preventing infection and accelerating healing—while also shifting the level of knowledge and expertise to perform dressing changes and treat the underlying wounds" (Toman, 2007, p. 135).

The trend of including OR experience in training continued into the 1960s. However, during the 1970s, a change occurred in nursing education, whereby nurses were expected to acquire a broad knowledge base. As a result, many schools eliminated OR experience from the curriculum, believing that it focused only on manual skills (Sandelowski, 2000). What was not recognized was the role that OR nurses play in ensuring patients' comfort and safety and continuity of care before, during, and after surgery.

In 1956 in the United States, the Association of Operating Room Nurses (AORN) was formed. The organization developed standards of nursing practice that outlined the perioperative nurse's scope of responsibility. AORN was the first nursing organization to develop structure, process, and outcome standards as defined by the American Nurses Association. AORN has since changed its name to the Association of Perioperative Registered Nurses; however, AORN is still used as its acronym. The organization continues to be a driving force for the practice of perioperative nursing and works closely with Canadian associations.

In Canada, the Operating Room Nurses Association of Canada (ORNAC) was founded in 1983. The mission of this professional organization is the promotion and advancement of excellence in the provision of perioperative care to patients and the professional growth and personal enhancement of perioperative registered nurses. It sets the standards for Canadian perioperative nursing practice. Specifically, ORNAC values are (1) knowledge—education and research are essential components that guide practice, (2) collaboration—with nurses within the specialty, organizations, agencies, and other disciplines, (3) respect—for worth, quality, diversity, and the importance of the patients and of each other, (4) professionalism—to advance the specialty, and (5) continuous quality improvement—to achieve excellence. Opportunities exist in conjunction with the Canadian Nurses Association for registered nurses to obtain perioperative nursing certification. In addition to the National Association of PeriAnesthesia Nurses of Canada (NAPANc), there are provincial associations. For example, the Ontario PeriAnesthesia Nurses Association (OPANA) was founded in 1985 to represent all nurses involved in the care of patients pre- and postanaesthesia. These nursing environments are usually same-day (ambulatory) care, postanaesthetic care units, and preadmission units.

OPANA (2009) has developed standards of perianaesthesia nursing practice that are used in Ontario hospitals.

Same-Day (Ambulatory) Surgery

A recent change in the surgical field is the advent of same-day surgery also referred to as *ambulatory surgery* or *short-stay surgery*. These services are provided within a hospital setting. More than half of all surgical procedures are conducted on an outpatient basis, including ophthalmic, gastroenterological, gynecological, otorhinolaryngologic, orthopedic, cosmetic and restorative, and general procedures. The incidence of **same-day surgery**, in which the patient is admitted on the day of surgery, has the surgery, and then goes home the same day, has greatly increased. The process of admitting patients and then observing them overnight (23-hour admission) can also occur.

There are distinct benefits for the patient who has same-day surgery. Anaesthesia drugs that metabolize rapidly with few after-effects allow for shorter operative times. Nurses recognize the benefit of early postoperative ambulation and encourage patients to assume an active role in recovery. Same-day surgery also results in shorter hospital stays, as patients are usually discharged the day of surgery. This reduces the possibility of developing hospital-acquired infections, which occur when patients become colonized with bacteria found in the hospital setting. Procedures such as tumour biopsies and gallbladder removal (**cholecystectomy**) can now be done using laparoscopic procedures. Because of the small incision required, a laparoscopic cholecystectomy involves a hospital stay of only a few to 24 hours and a recovery period of a week. In contrast, a traditional open cholecystectomy requires a larger abdominal incision and involves a hospital stay of three to five days and a recovery period of at least four weeks. Thus, many surgeons use laparoscopic procedures for a variety of surgical interventions, thereby decreasing the length of surgery, hospitalization, and associated costs. Laparoscopic approaches are just one form of the increasingly used minimally invasive surgical techniques (MIS). For example, specialized instruments and cameras can be used for procedures such as pyeloplasty (Francis & Winfield, 2006) or total hip arthroscopy (Burden, 2007). Construction of new operating room suites is increasingly providing dedicated rooms for MIS, and thus OR nurses are being educated regarding their role related to the techniques as well as intraoperative patient care.

Same-day surgery requires that nurses provide extensive preoperative and postoperative teaching and assess the patient's available support systems and readiness for self-care. For example, discharge education should include potential complications and what to do about them, instructions on care of incision sites and any drains, diet and activity, telephone numbers to contact, and managing pain. Surgical day care nurses frequently call patients at home on the day after surgery to inquire about how recovery is progressing. As well, home care nurses must refer the patient to appropriate community agencies or services such as physiotherapy.

Scientific Knowledge Base

Classification of Surgery

Surgical procedures are classified according to seriousness, urgency, and purpose (Table 48-1). A procedure may fall into more than one classification. For example, surgical removal of a disfiguring scar is minor in seriousness, elective in urgency, and reconstructive in purpose. Frequently, the classes overlap.

An urgent procedure is also considered major in seriousness. As well, the same operation may be performed for different reasons on different patients. For example, a gastrectomy may be performed as an emergency procedure to resect a bleeding ulcer or as an urgent procedure to remove a cancerous growth. The classification indicates to you the level of care a patient might require. Hospitals have a system for prioritizing the booking of surgeries based on their classification.

The American Society of Anesthesiologists (ASA) assigns classification on the basis of a patient's physiological condition, independent of the proposed surgical procedure (Table 48-2). Intraoperative difficulties occur more frequently with patients who have a poor physical status classification (Rothrock, 2003). ASA physical status class I and class II patients are acceptable for ambulatory surgery. Patients in classes IV and V require inpatient surgery because they are at higher risk for complications (e.g., cardiac or pulmonary complications). The ASA classification system is used in Canadian hospitals.

Nursing Knowledge Base

Nursing knowledge offers important contributions for the care of the perioperative patient. For example, nursing research has shown the benefit of preoperative education in promoting positive patient outcomes after surgery. Structured preoperative teaching that includes, for example, the AORN (2004) standards and a return demonstration of postoperative exercises has been shown to improve outcomes such as pain severity, pulmonary function, length of stay, and patients' levels of anxiety.

Significant evidence-based knowledge is also available for proper wound care interventions. Nursing research has contributed to what is known about the characteristics of wound healing and the types of applications most likely to be beneficial (see Chapter 46).

Within the OR setting, knowledge has improved the standards for infection control and patient safety. For example, surgical hand scrubs (see Chapter 32) can now be performed without the use of brushes as a result of research that has shown the efficacy of alcohol-based hand antiseptics in reducing bacteria on the skin (Hobson et al., 1998). Evidence-based practice changes within the OR improve the quality of care for surgical patients and ultimately improve patient outcomes.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, information gathered from patients, experience, critical thinking qualities, and intellectual and professional standards. Clinical judgements require you to anticipate the information necessary, analyze the data, and make decisions regarding patient care. A patient's condition is always changing. During assessment (Figure 48-1), you must consider all of the elements that contribute to making appropriate nursing diagnoses.

When caring for the perioperative patient, you make clinical care decisions by integrating knowledge of anatomy, physiology, pathophysiology, and the surgical stress response with previous experiences in caring for surgical patients and information gathered from the patient, such as medical and surgical history, potential for surgical risk, and coping resources. Your use of critical thinking qualities such as perseverance is needed to develop a plan of care that provides successful perioperative

► **TABLE 48-1** Classification of Surgical Procedures

Type	Description	Examples
Seriousness		
Major	Involves extensive reconstruction or alteration in body parts; poses great risks to well-being	Coronary artery bypass, colon resection, removal of larynx, resection of lung lobe
Minor	Involves minimal alteration in body parts; often designed to correct deformities; involves minimal risks compared with major procedures	Cataract extraction, facial plastic surgery, tooth extraction
Urgency		
Elective	Is performed on basis of patient's choice; is not essential and may not be necessary for health	Bunionectomy, facial plastic surgery, hernia repair, breast reconstruction
Urgent	Is necessary for patient's health; may prevent additional problems from developing (e.g., tissue destruction or impaired organ function); not necessarily emergency	Excision of cancerous tumour, removal of gallbladder for stones, vascular repair for obstructed artery (e.g., coronary artery bypass)
Emergency	Must be done immediately to save life or preserve function of body part	Repair of perforated appendix, repair of traumatic amputation, control of internal hemorrhaging
Purpose		
Diagnostic	Surgical exploration that allows physician to confirm diagnosis; may involve removal of tissue for further diagnostic testing	Exploratory laparotomy (incision into peritoneal cavity to inspect abdominal organs), breast mass biopsy
Ablative	Excision or removal of diseased body part	Amputation, removal of appendix, cholecystectomy
Palliative	Relieves or reduces intensity of disease symptoms; will not produce cure	Colostomy, debridement of necrotic tissue, resection of nerve roots
Reconstructive or restorative	Restores function or appearance to traumatized or malfunctioning tissues	Internal fixation of fractures, scar revision
Procurement for transplant	Removal of organs, tissues, or both from a person pronounced brain dead for transplantation into another person	Kidney, heart, or liver transplant
Constructive	Restores function lost or reduced as result of congenital anomalies	Repair of cleft palate, closure of atrial septal defect in heart
Cosmetic	Performed to improve personal appearance	Blepharoplasty to correct eyelid deformities; rhinoplasty to reshape nose

► **TABLE 48-2** Physical Status (PS) Classification of the American Society of Anesthesiologists

Class	Description	Characteristics and Examples
PS-I	A normal, healthy patient	No physiological, biological, or organic disturbance
PS-II	A patient with a mild systemic disease	Disease imposes minimal restriction on activity; e.g., hypertension (HTN), obesity, diabetes mellitus
PS-III	A patient with a severe systemic disease that limits activity but is not incapacitating	Disease limits activity (e.g., severe diabetes with systemic complications); history of myocardial infarction, angina pectoris, or poorly controlled HTN
PS-IV	A patient with a severe systemic disease that is a constant threat to life	Severe cardiac, pulmonary, renal, hepatic, or endocrine dysfunction
PS-V	A moribund patient who is not expected to survive without the operation	Surgery is done as a last recourse or as a resuscitative effort; e.g., major multisystem or cerebral trauma, ruptured aneurysm, or large pulmonary embolus
PS-VI	A patient declared brain dead whose organs are being removed for donor purposes	

Note: The addition of an "E" to the physical status class indicates emergency surgery, such as PS-IE, PS-IIE, and so on.

care (e.g., airway management, infection control, pain management, and discharge planning). Professional standards and guidelines developed by, for example, AORN, NAPANC, OPANA, and ORNAC, provide valuable information for perioperative management and evaluation of processes and outcomes. However, you also should review guidelines within the context of new and emerging evidence-informed practice and agency policies.

The Nursing Process in the Preoperative Surgical Phase

Surgical patients enter the health care setting in different stages of health. A patient may enter the hospital on a predetermined day feeling relatively healthy and prepared to face elective surgery. In contrast, a victim of a motor vehicle collision may face emergency surgery with no time to prepare. The ability to

Figure 48-1 Critical thinking model for surgical patient assessment.

establish rapport and maintain a professional relationship with the patient is an essential component of the preoperative phase. You must do this quickly but compassionately and effectively.

The surgical patient may undergo tests and procedures to confirm or rule out problems requiring surgery. Most testing is performed before the day of surgery. Usually patients scheduled for same-day surgery have tests done several days before surgery. Testing done the day of surgery is usually limited to such tests as glucose monitoring for the patient with diabetes. You must be familiar with the tests, their purpose, and how to monitor results.

The patient meets many members of the interprofessional team, including surgeons, anesthesiologists, physiotherapists, and nurses. All play a role in the patient's care and recovery. Family members attempt to provide support through their presence but face many of the same stressors as the patient. You must communicate effectively with the patient and family because the nurse-patient relationship is the foundation of care (see Chapter 17). You should assess the patient's physical, emotional, and spiritual well-being and cultural heritage; recognize the degree of surgical risk; coordinate diagnostic tests; identify nursing diagnoses and nursing interventions; and establish outcomes in collaboration with the patient and his or her family. Pertinent data and the care plan are communicated among the members of the surgical team.

❖ Assessment

The assessment of the surgical patient is intended to establish the patient's baseline preoperative function to assist in preventing and recognizing possible postoperative complications. Assessment of the surgical patient can be extensive. Ambulatory surgical programs require that patient data be completed several days in advance. An interprofessional team approach is essential. Patients are admitted only hours before the surgical event; thus, you must organize and verify data obtained preoperatively to implement a perioperative care plan. This occurs not only with the ambulatory care patient, but also with the patient who will require a more prolonged hospital stay. Increasingly, patients are admitted on the day of surgery, even for such major procedures as open heart surgery and bowel surgery.

Most assessments begin in a preadmission clinic before admission for surgery. The purpose of the preadmission is to prepare the patient physically and emotionally for surgery (OPANA, 2009). Patients may answer a self-report inventory and you may complete an initial physical examination, draw blood or complete other laboratory tests, begin teaching, identify potential risks, and answer questions. This streamlines the care required for the patient on the day of surgery. In the immediate preoperative period, you assess the patient's understanding of previous teaching and individualize patient and family care.

The physician usually performs a comprehensive history and physical examination with follow-up by the preadmission nurse. In this case, you need to review assessments and testing already completed and to highlight significant information (e.g., the patient being on diuretics). You focus on key measurements for all body systems to ensure that no obvious problems are overlooked and that the patient has understood education previously provided. Even though the surgeon will screen the patient before scheduling surgery, preoperative assessment occasionally reveals an abnormality that delays or cancels surgery. For example, the patient may have a cough and low-grade fever on admission. This may indicate the onset of infection, and the surgeon will need to be notified immediately.

Nursing Health History

You should conduct an initial interview to collect a patient history similar to that described in Chapter 31. If a patient is unable to relate all the necessary information, you should rely on family members as resources.

Medical History

A review of the patient's medical history should include past illnesses and the primary reason for currently seeking medical care. The patient's current medical record and medical records from past hospitalizations are excellent sources of data.

Preexisting illnesses can influence the choice of anesthetic agents used and the patient's ability to tolerate surgery and reach full recovery (Table 48-3). Candidates for same-day surgery must be carefully screened for medical conditions that may increase the risk for complications during or after surgery. For example, a patient who has a history of heart failure may experience a further decline in cardiac function both intraoperatively and postoperatively. Intravenous (IV) fluids may need to be administered at a slower rate, or a diuretic may need to be given if blood transfusions are required.

► **TABLE 48-3** Medical Conditions That Increase Risks of Surgery

Type of Condition	Reason for Risk
Bleeding disorders (thrombocytopenia, hemophilia) Diabetes mellitus	Increase risk of hemorrhaging during and after surgery. Increases susceptibility to infection and may impair wound healing due to altered glucose metabolism and associated circulatory impairment. Stress of surgery may cause increases in blood glucose levels.
Heart disease (recent myocardial infarction, dysrhythmias, congestive heart failure) and peripheral vascular disease Obstructive sleep apnea	Stress of surgery causes increased demands on myocardium to maintain cardiac output. General anaesthetic agents depress cardiac function. Administration of opioids increases risk of airway obstruction postoperatively. Patients will desaturate as revealed by drop in oxygen saturation by pulse oximetry.
Upper respiratory infection	Increases risk of respiratory complications during anaesthesia (e.g., pneumonia and spasm of laryngeal muscles).
Liver disease	Alters metabolism and elimination of drugs administered during surgery and impairs wound healing and clotting time because of alterations in protein metabolism.
Fever	Predisposes patient to fluid and electrolyte imbalances and may indicate underlying infection.
Chronic respiratory disease (emphysema, bronchitis, asthma)	Reduces patient's means to compensate for acid-base alterations (see Chapter 39). Anaesthetic agents reduce respiratory function, increasing risk for severe hypoventilation.
Immunological disorders (leukemia, acquired immune deficiency syndrome [AIDS], bone marrow depression, and use of chemotherapeutic drugs or immunosuppressive agents) Abuse of street drugs	Increase risk of infection and delayed wound healing after surgery. Patients who abuse drugs may have underlying disease (HIV, hepatitis), which can affect response to anaesthesia and surgery and the healing process.
Chronic pain	Regular use of pain medications may result in higher tolerance, a reduced effect from repeated doses of the same analgesic class (Ferrell & Coyle, 2001). Increased doses of analgesics may be required to achieve postoperative pain control.

Risk Factors

Various conditions and factors increase a person's risk when undergoing surgery. Knowledge of risk factors enables you to take necessary precautions in planning care.

Age. Very young patients are at risk during surgery because of their immature physiological status. During surgery, nurses and physicians are especially concerned with maintaining an infant's normal body temperature. The infant's shivering reflex is underdeveloped, and often wide temperature variations occur. Anaesthesia adds to the risk because anaesthetics can cause vasodilation and heat loss.

During surgery, an infant has difficulty maintaining a normal circulatory blood volume. The total blood volume of an infant is considerably less than that of an older child or an adult. Therefore, even a small amount of blood loss can be serious. A reduced circulatory volume makes it difficult for the infant to respond to increased oxygen demands during surgery. In addition, the infant is highly susceptible to complications associated with dehydration. However, if blood or fluids are replaced too quickly, overhydration may occur. Other important and unique aspects of a child's surgical care are airway management, treatment of seizures, management of temperature alterations, identification and treatment of emergence delirium and delayed emergence from anaesthesia, treatment of pain and agitation, and availability of age-appropriate emergency equipment and medications.

Older patients are also at risk for complications. With advancing age, a patient's physical capacity to adapt to the stress of surgery is hampered because of a decline in certain

body functions such as renal and liver. Despite the risk, the majority of patients undergoing surgery are older adults. Table 48-4 summarizes the physiological factors that place older patients at risk during surgery.

Nutrition. Normal tissue repair and resistance to infection depend on adequate nutrients. Surgery intensifies this need. After surgery, a patient requires at least 1500 kcal/day to maintain energy reserves. Increased protein, vitamins A and C, and zinc facilitate wound healing (see Chapters 42 and 46). A malnourished patient is prone to poor tolerance of anaesthesia, negative nitrogen balance, delayed blood clotting mechanisms, infection, poor wound healing, and the potential for multiple organ failure. If a patient is having elective surgery, attempts to correct nutritional imbalances should be made before the surgery. However, if a malnourished patient must undergo an emergency procedure, efforts to restore nutrients will occur after surgery.

Obesity. Obesity increases surgical risk by reducing respiratory and cardiac functions. Hypertension, coronary artery disease, diabetes mellitus, and heart failure are common in the bariatric (obese) population. Embolus, atelectasis (partial or total collapse of the alveoli), and pneumonia are also more frequent postoperative complications in the obese patient. The patient may have difficulty resuming normal physical activity after surgery. The obese patient is susceptible to poor wound healing and wound infection because of the structure of fatty tissue, which contains a poor blood supply. This slows delivery of essential nutrients, antibodies, and enzymes needed for wound healing (see Chapter 42). It is often

► **TABLE 48-4** Physiological Factors That Place the Older Adult at Risk During Surgery

Alterations	Risks	Nursing Implications
Cardiovascular System		
Degenerative change in myocardium and valves	Reduced cardiac reserve	Assess baseline vital signs. Recognize the longer time period required for heart rate to return to normal after stress on the heart and evaluate the occurrence of tachycardia accordingly (Eliopoulos, 2001).
Rigidity of arterial walls and reduction in sympathetic and parasympathetic innervation to heart	Alterations predispose patient to postoperative hemorrhage and rise in systolic and diastolic blood pressure	Maintain adequate fluid balance to minimize stress to the heart. Ensure that blood pressure level is adequate to meet circulatory demands.
Increase in calcium and cholesterol deposits within small arteries; thickened arterial walls	Predispose patient to clot formation in lower extremities	Instruct patient on techniques for performing leg exercises and proper turning. Apply elastic stockings, sequential compression devices.
Integumentary System		
Decreased subcutaneous tissue and increased fragility of skin	Prone to pressure ulcers and skin tears	Assess skin at least every four hours; pad all bony prominences during surgery. Turn or reposition at least every two hours (see Chapter 46).
Pulmonary System		
Stiffening and reduction in size of the rib cage	Reduced vital capacity	Instruct patient on proper technique for coughing and deep breathing.
Reduced range of movement in diaphragm	Residual capacity (volume of air left in lung after normal breath) increases, reducing amount of new air brought into lungs with each inspiration	When possible, have patient ambulate and sit in chair frequently.
Stiffened lung tissue and enlarged air spaces	Alteration reduces blood oxygenation	Obtain baseline oxygen saturation; measure as indicated throughout perioperative period.
Renal System		
Reduced blood flow to kidneys	Increased risk of shock when blood loss occurs	For patients hospitalized before surgery, determine baseline urinary output for 24 hours.
Reduced glomerular filtration rate and excretory times	Limits ability to eliminate drugs or toxic substances	Assess for adverse response to drugs.
Reduced bladder capacity	Voiding frequency increases, and larger amount of urine stays in bladder after voiding. Sensation of need to void may not occur until bladder is filled.	Instruct patient to notify nurse immediately when sensation of bladder fullness develops. Keep call light and bedpan within easy reach. Toilet every two hours, or more frequently if indicated.
Neurological System		
Sensory losses, including reduced tactile sense	Decreased ability to respond to early warning signs of surgical complications	Inspect bony prominences for signs of pressure that patient may not sense. Orient patient to surrounding environment. Observe for nonverbal signs of pain.
Decreased reaction time	Confusion after anaesthesia. Delirium postoperatively is an acute confusional state with rapid onset, disturbance in consciousness, and change in cognition (Hogan et al., 2006). Delirium can be caused by medications such as narcotics, or by physiological reasons such as infection or dehydration.	Allow adequate time to respond, process information, and perform tasks. Institute Best Practice Guidelines (BPGs) on screening for and on caregiving strategies for older adults with delirium, dementia, and depression (Registered Nurses' Association of Ontario [RNAO], 2004a, 2004b). Institute fall precautions (RNAO, 2002b).
Metabolic System		
Lower basal metabolic rate	Reduced total oxygen consumption	Ensure adequate nutritional intake when diet is resumed, but avoid intake of excess calories.
Reduced number of red blood cells and hemoglobin levels	Ability to carry adequate oxygen to tissues is reduced	Administer blood products if required. Monitor blood test results.

Continued

► **TABLE 48-4** Physiological Factors That Place the Older Adult at Risk During Surgery—cont'd

Alterations	Risks	Nursing Implications
Change in total amounts of body potassium and water volume	Greater risk for fluid or electrolyte imbalance occurs	Monitor electrolyte levels and supplement as necessary.
Impaired thermoregulatory mechanisms	Cold operating rooms; exposure of body parts during procedure, IV fluids, medications	Ensure careful, close monitoring of patient temperature; provide warm blankets; monitor cardiac function; warm IV fluids.

difficult to close the surgical wound of an obese patient because of the thick adipose layer. An obese patient is also at risk for **dehiscence** (opening of the suture line).

Immunocompetence. For the patient with cancer, radiation therapy may be given preoperatively to reduce the size of the cancerous tumour so that it can be removed surgically. Radiation has some unavoidable effects on normal tissue, such as excess thinning of skin layers, destruction of collagen, and impaired vascularization of tissue. Ideally, the surgeon waits four to six weeks after completion of radiation treatments to perform surgery. Otherwise, the patient may face serious problems with wound healing. In addition, chemotherapeutic drugs used for cancer treatment, immunosuppressive medications used to prevent rejection after organ transplantation, and steroids used to treat a variety of inflammatory conditions increase the risk for infection.

Fluid and Electrolyte Imbalances. The body responds to surgery as if it is a form of trauma. As a result of the adrenocortical stress response, sodium and water are retained and potassium is lost within the first two to five days after surgery. The severity of the stress response influences the degree of fluid and electrolyte imbalances. The more extensive the surgery, the greater is the stress response. A patient who is hypovolemic or who has serious preoperative electrolyte alterations is at significant risk during and after surgery. For example, an excess or depletion of potassium increases the chance of dysrhythmia during or after surgery. If the patient has preexisting renal, gastrointestinal, or cardiovascular abnormalities, the risk for fluid and electrolyte alterations is even greater.

Pregnancy. The perioperative care plan must address the needs of both the mother and the developing fetus. Surgery is performed on a pregnant patient only on an emergency basis. All the mother's major systems are affected during pregnancy. For example, cardiac output significantly increases, as does respiratory tidal volume to accommodate the increase in metabolic rate. Gastrointestinal motility decreases, hormone levels increase, and energy levels decrease with advancing pregnancy. Laboratory and hemodynamic values change. Fibrinogen levels increase, making pregnant patients more susceptible to the development of deep vein thrombosis because of increased coagulability. Hemoglobin and hematocrit levels decrease, mostly as a result of the effects of hemodilution (increased circulating volume). The white blood cell (WBC) count is elevated when the woman is near term and postpartum without the presence of infection. However, infection always must be ruled out in the presence of an elevated WBC count. General anaesthesia is administered with caution because of the increased risk for fetal death and preterm labour. Psychological considerations for mother and family are essential.

Previous Surgeries

Although previous surgery does not necessarily present as a risk factor, a patient's past experience with surgery can highlight many potential issues. You should ask the patient to recall the previous type of surgery, level of discomfort, extent of disability, and overall level of care provided. Address any complications that the patient experienced. It is also important to assess patients for motion sickness, nausea, and vomiting with previous surgeries (Gan, 2002; Tramer, 2001). These factors increase the risk for aspiration. Prior anaesthesia records may be a useful source of information if previous problems such as malignant hyperthermia occurred. This information helps you to anticipate the patient's preoperative and postoperative needs.

Previous surgery also may influence the level of physical care required after a surgical procedure. For example, a patient who has had a previous thoracotomy for resection of a lung lobe has a greater risk for postoperative pulmonary complications than does a patient with intact, normal lungs.

Perceptions and Understanding of Surgery

The surgical experience affects not only the patient, but also the entire family. You therefore must prepare both the patient and the family for the surgical experience. Identifying a patient's and family's knowledge, expectations, and perceptions allows you to plan teaching and to provide individualized emotional support measures.

Each patient feels fearful when entering the surgical setting. Some fears are due to past hospital experiences, warnings received from friends and family, or lack of knowledge. You must assess the patient's understanding of the planned surgery and its implications. For example, you need to determine whether the patient recognizes that she will have a breast biopsy performed, not a mastectomy. You might ask questions such as "Tell me what you think will happen before and after surgery," or "Explain what you know about your surgery." If a patient is misinformed or unaware of the reason for surgery, you must confer with the physician before the patient is sent to the surgical suite. You also determine whether further explanations are needed related to routine preoperative and postoperative procedures. When a patient is well prepared and knows what to expect, you reinforce the patient's knowledge and maintain accuracy and consistency.

Medication History

If a patient regularly uses prescription or over-the-counter medications, the surgeon or anaesthesiologist may temporarily discontinue the drugs before surgery or adjust the dosages. Certain medications have special implications for the surgical patient, creating greater risks for complications or interacting negatively with anaesthetic agents (Table 48-5). For example,

TABLE 48-5 Medications With Special Implications for the Surgical Patient

Drug Class	Effects During Surgery
Antibiotics	Antibiotics can potentiate action of anaesthetic agents. For example, if taken within two weeks before surgery, aminoglycosides (gentamicin, tobramycin, neomycin) may cause mild respiratory depression due to depressed neuromuscular transmission.
Antidysrhythmics	Antidysrhythmics can reduce cardiac contractility and impair cardiac conduction during anaesthesia.
Anticoagulants	Anticoagulants alter normal clotting factors and thus increase risk of hemorrhaging. They should be discontinued before surgery. Aspirin (ASA) is a commonly used medication that can alter clotting mechanisms. Many older patients take ASA, and the nurse should be alert as to whether they have discontinued this presurgery. Most surgeons will have the patient stop taking ASA four to five days previous to the surgery.
Anticonvulsants	Long-term use of certain anticonvulsants (e.g., phenytoin [Dilantin] and phenobarbital) can alter the metabolism of anaesthetic agents.
Antihypertensives	Antihypertensives may interact with anaesthetic agents to cause bradycardia, hypotension, and impaired circulation. Some may inhibit synthesis and storage of norepinephrine in sympathetic nerve endings.
Corticosteroids	With prolonged use, corticosteroids cause adrenal atrophy, which reduces the body's ability to withstand stress. Before and during surgery, dosages may be temporarily increased.
Insulin	Diabetic patients' need for insulin after surgery is altered. Stress response and IV administration of glucose solutions can increase dosage requirements after surgery. Decreased nutritional intake can decrease dosage requirements.
Diuretics	Diuretics potentiate electrolyte imbalances (particularly potassium) after surgery.
Nonsteroidal anti-inflammatory drugs (NSAIDs)	NSAIDs inhibit platelet aggregation and may prolong bleeding time, increasing susceptibility to postoperative bleeding.
Herbal therapies: ginger, ginkgo, ginseng	Some herbal therapies have the ability to affect platelet activity and increase susceptibility to postoperative bleeding. Ginseng may increase hypoglycemia with insulin therapy.

you instruct patients in a preadmission unit to ask the physician whether usual medications should be taken on the morning of surgery. Patients also should be asked whether any herbal preparations are used, because many patients do not view herbs as medications and may omit them from their medication history (see Chapter 34). Certain herbs may interfere with the action of other medications (a pharmacist must be consulted). In the preadmission clinic, you determine whether the patient is taking any herbal medications. For hospitalized patients, prescription drugs taken preoperatively are automatically discontinued postoperatively unless the physician reorders them. It is important for you to be aware of the patient's previous medications that likely will need to be resumed postoperatively (e.g., antihypertensives).

Allergies

You must assess for allergies to drugs that may be given during a phase of the surgical experience. In addition, it is critical to assess for latex, food, and contact allergies (e.g., allergies to tape, ointments, or solutions). A patient may be too young or have too few exposures to drugs to know whether he or she has any allergies. The type of allergic response is also very important to assess. Allergies need to be delineated from unpleasant side effects. For example, the patient may state that codeine causes nausea (a side effect), or that it causes hypotension and confusion (an allergy). When asking a patient about allergies, realize that the term *allergy* can be confusing for some patients. Asking a patient whether he or she has ever "had a problem with a medication or substance" may be another helpful approach to questioning.

It is critical that the patient be asked specifically about latex allergies because a latex-free environment must be provided for patients with latex allergies. You ensure that a list of the patient's allergies is noted appropriately in his or her chart, the hospital computer system, or both, as well as in any

other places designated by institutional policy, such as an allergy band.

Smoking Habits

The patient who smokes is at greater risk for postoperative pulmonary complications than one who does not. The chronic smoker already has an increased amount and thickness of mucous secretions in the lungs. General anaesthetics increase airway irritation and stimulate pulmonary secretions, which are retained as a result of reduction in ciliary activity during anaesthesia. After surgery, the patient who smokes has greater difficulty clearing the airways of mucous secretions and needs education on the importance of postoperative deep breathing and coughing (see Chapter 38). In addition, smoking can compromise blood flow to the heart, which can affect the response to surgery. Nurses play a key role in reducing smoking, and there are nursing Best Practice Guidelines (BPGs) on smoking cessation (RNAO, 2007). During the postoperative period, nicotine replacement therapy may be required to support the patient who smokes.

Alcohol Ingestion and Substance Use and Abuse

Habitual use of alcohol and illegal drugs predisposes the patient to adverse reactions to anaesthetic agents. The patient also may experience a cross-tolerance to anaesthetic agents, necessitating higher-than-normal amounts. In addition, the physician may need to increase postoperative dosages of analgesics. Patients with a history of excessive alcohol ingestion also may be malnourished, which may contribute to delayed wound healing. These patients are also at risk for liver disease, portal hypertension, and esophageal varices (predisposing the patient to bleeding disorders). The patient who habitually uses alcohol and is required to remain in the hospital for longer than 24 hours is also at risk for acute alcohol withdrawal and its more severe form, delirium tremens.

Family Support

It is important for you to determine the extent of the patient's support from family members or friends. Because blood relations do not always define family, it is best to have the patient identify his or her sources of support (see Chapter 19). Surgery often results in temporary or permanent disability that requires added assistance during recovery. The patient usually cannot immediately assume the same level of physical activity enjoyed before surgery. Often a patient returns home with dressings to change or exercises to perform. With same-day surgery, patients and families assume responsibility for postoperative care. The family is an important resource for the patient with physical limitations and provides the emotional support needed to motivate the patient to return to a previous state of health. In addition, the family may better remember preoperative and postoperative teaching.

You should ask whether family members or friends could provide support. The patient may want someone else present when you provide instructions or explanations. Family presence should be encouraged when feasible, especially for patients having ambulatory surgery. Often a family member can become the patient's coach, offering valuable support during the postoperative period, when the patient's participation in care is vital.

Occupation

Surgery may result in physical alterations that hinder or prevent a person from returning to work. You should assess the patient's occupational history to anticipate the possible effects of surgery on recovery and eventual work performance. Explain any restrictions before a patient returns to work, such as lifting, use of the extremities, or climbing stairs. When a patient is unable to return to his or her job, you should confer with a social worker or occupational therapist to refer the patient to job-training programs or to help the patient seek economic assistance.

Preoperative Preparation for Pain Assessment and Management

Surgical manipulation of tissues, treatments, and positioning on the OR table may result in postoperative pain for the patient. Pain is a very personal experience and requires an individualized care plan. Preoperatively, you should prepare the patient and family for the assessment and management of pain (see Chapter 41), including the patient's and the family's expectations for pain management after surgery. You should begin education regarding pain management as soon as possible (Barnes, 2001). The preoperative assessment should introduce to the patient the use of a pain instrument to rate the presence and severity of pain postoperatively (see Chapter 41). Several instruments for both pediatric and adult patients have shown reliability and validity (Summers, 2001). Frequent pain assessments with the patient are necessary to alert you to treat the pain and assess the adequacy (outcome) of pain interventions.

Review of Emotional Health

Surgery is psychologically stressful. The patient may be anxious about the surgery and its implications. Patients often feel that they are powerless over their situation. Family members may perceive the patient's surgery as a disruption of their lifestyle. Hospitalization and the recovery period at home may be lengthy. The family is usually concerned about the

patient returning to a normal, productive life. When the patient has chronic illness, the family may be fearful that surgery will result in further disability or may be hopeful that it will improve their lifestyle. To understand the impact of surgery on a patient's and a family's emotional health, you should assess the patient's feelings about surgery, self-concept, body image, and coping resources.

It is often difficult to assess feelings thoroughly when ambulatory surgery is scheduled. You usually have less time to establish a relationship with the patient. Box 48-1 describes a study that explored the needs of ambulatory surgery patients. In some day surgical programs, you may visit with a patient in the home or on the telephone before surgery. In a hospital room, you should choose a time for discussion after admitting procedures or diagnostic tests have been completed. Explain to the patient that it is normal to have fears and concerns. The patient's ability to share feelings partially depends on your willingness to listen, be supportive, and clarify misconceptions.

If the patient feels powerless, you should attempt to determine the reason. The medical diagnosis may generate apprehension of increased dependence and loss of physical or mental function. The thought of being "put to sleep" under anaesthesia may create concern about loss of control. Most patients want to retain the power to make decisions about treatment. You must assure patients of their right to ask questions and seek information.

A patient may be angry about the need for surgery. For example, a young person may feel that it is unfair to have a disorder that typically affects older people. Surgery may occur at a time when it is inconvenient or potentially disruptive. The patient occasionally may express anger verbally at you or the physician. Being argumentative or overly demanding, refusing to cooperate, and criticizing your efforts to provide care are manifestations of the patient's anger and anxiety.

Body Image. Surgical removal of any diseased body part may leave permanent disfigurement or alteration in body function. Loss of certain body functions (e.g., with a colostomy or ureterostomy) may compound patients' fears. You should assess for the body-image alterations that patients perceive will result from surgery. Patients will respond differently depending on their culture, self-concept, and degree of self-esteem (see Chapter 25).

Often, surgery changes the physical or psychological aspects of patients' sexuality. Excision of breast tissue, colostomy, ureterostomy, hysterectomy, or removal of the prostate gland may affect the patients' perceptions of their sexuality. Some surgeries (e.g., hernia repairs) require the patient to refrain from sexual intercourse temporarily, until the return to normal physical activity.

You should encourage patients to express their concerns about sexuality. The patient facing even temporary sexual dysfunction requires understanding and support. Discussions about the patient's sexuality should be held with the patient's sexual partner so that both individuals can gain a shared understanding of how to cope with limitations in sexual function.

Coping Resources. Assessment of feelings and self-concept helps to reveal whether the patient can cope with the stress of surgery. The physiological effects of stress are well documented. Activation of the endocrine system results in the release of hormones and catecholamines (epinephrine, norepinephrine), which results in increases in blood pressure, heart rate, and respiration. Platelet aggregation also occurs, along

* BOX 48-1 RESEARCH HIGHLIGHT

Pain Management Following Discharge After Ambulatory Same-Day Surgery

Research Focus

Same-day surgeries are now commonplace for many procedures. What is not well known is how patients manage their pain once home following same-day surgery.

Research Abstract

The purpose of the study by Watt-Watson et al. (2004) was to examine the perspectives of patients who had undergone same-day surgery. The focus of the telephone interview with 180 patients was to determine the level of their pain, how much their pain interferes with usual activities, analgesics used, adverse events, complications and resources utilized, and the adequacy of post-discharge information given. Four periods were examined: 24, 48, and 72 hours post-discharge and then 7 days after discharge.

The sample of 180 patients was made up of those who had undergone laparoscopic cholecystectomy (54), hand surgery (78), and shoulder surgery (48). The average age of the patients was 42 years (youngest was 27 and oldest was 57). Patients requiring hand surgery received regional anaesthesia, while those receiving laparoscopic cholecystectomy had a general anaesthesia. Those patients undergoing shoulder surgery had a general anaesthesia with some having a postoperative block for pain. Statistical analysis was conducted to determine differences in pain, interference, and analgesic use by surgical group and time since surgery. An alpha level of significance of 0.05 was used for the analysis. The results revealed that pain decreased more quickly for patients with hand surgery and laparoscopic cholecystectomy, particularly at the 72 hours and 7 day time frame. However, at day 7, the "worst 24-hour pain" was reported as severe by 31% (7) of patients with hand surgery, 55% with shoulder surgery, and 8% with laparoscopic cholecystectomy. In addition, patients with shoulder surgery had significantly more pain and pain-related interference with sleep and work from 24 hours after surgery until day 7. The main analgesic taken was acetaminophen with codeine 30 mg. Fifty percent of the sample took no analgesics after 72 hours postoperative. About 20% of patients experienced adverse effects, mainly constipation and nausea from the analgesics. Less than 6% of the sample tried nonpharmacological approaches for their pain. Complications cited by the patients were bleeding (4%) and sore throat (11%). The physician was called by 4% of the sample. Most patients (69%) reported that they did receive adequate information to take care of themselves after surgery. However, 23% of the patients receiving shoulder surgery did not believe they had received enough information. Seventy-three percent were prepared enough to manage their pain at home while 55% felt instructions were clear about taking medications. However, 56% of the sample indicated that they did not receive instructions regarding what to do if the analgesics were ineffective or if they caused side effects.

The authors concluded that despite the pain reported by the patients, analgesic use and other interventions were minimal. Further research into pain interventions and related education for day-surgery patients after discharge is warranted.

with many other physiological responses. You must be aware of these responses and assist with stress management (see Chapter 29). Ask the patient about past stress management. If the patient has had previous surgery, you should determine what behaviours helped to resolve any tension or nervousness. You may instruct the patient on relaxation exercises that can help control anxiety.

When reviewing the patient's coping resources, ask him or her about specific family members and friends who may provide support. Once they are identified, you should include these individuals in any patient teaching and interventions aimed at managing stress and anxiety.

Culture

Culture is a patterned behavioural response that has developed over time through social and religious structures, as well as intellectual and artistic manifestations (Giger & Davidhizar, 1999). Patients come from diverse cultural and religious backgrounds that affect the way they perceive and react to their surgical experience. If cultural, ethnic, and religious differences are not acknowledged and incorporated into the perioperative care plan, desired surgical outcomes may not be achieved. Therefore, learning about a patient's cultural and ethnic heritage helps you provide effective perioperative care. Although it is important to recognize and plan for differences based on culture, you also must recognize that members of the same culture are individuals and may not hold these shared beliefs. Box 48-2 highlights cultural care aspects in the perioperative period.

* BOX 48-2 CULTURAL ASPECTS OF CARE

Providing individualized education and perioperative nursing care to patients of various cultural, religious, and ethnic groups can be challenging. Using a variety of resources available within a health care agency, both in the literature and from the Internet, will help you to provide culturally sensitive care.

Implications for Practice

- Preoperative assessment should include a cultural assessment with questions such as primary language spoken, feelings regarding surgery and pain, pain management, expectations, support system, and feelings toward self-care with postoperative implications (e.g., Does patient relate to concept of pain? Does patient follow custom that gives family members control over decisions?).
- Use a professional interpreter to communicate with a patient whose language is different than yours.
- Use pictures or phrase cards with various languages to communicate with a patient whose language is different than yours; these cards can be used to assess pain, comfort, temperature, and so forth. For example, Davidhizar and Giger (2004) suggest strategies for culturally appropriate assessment and management of pain such as understanding that the meaning of pain varies between cultures.
- Provide preoperative and postoperative educational materials in a variety of languages.

Pain as the fifth vital sign: Will cultural variations be considered? *Journal of Transcultural Nursing*, 10, 285.

Patient Expectations

Patients rely on their caregivers for information, comfort, pain control, adequate monitoring, and performance of interventions that ensure their safety throughout the surgical experience. This requires you to have a caring attitude, advocate for the patient, be skilled in surgical assessment and interventions, and anticipate the patient's needs throughout the perioperative period. You must understand the patient's expectations in order to develop an individualized care plan. Does the patient expect full pain relief or simply to have pain reduced? Does the patient expect to be independent immediately after surgery, or does he or she expect to be fully dependent on you or on family members? These are only a few of the questions that need to be asked of the surgical patient to establish a care plan congruent with his or her needs and expectations.

Physical Examination

You should conduct a partial or complete physical examination, depending on the patient's preoperative condition (see Chapter 31). Assessment focuses on findings related to the patient's medical history and on body systems that likely will be affected by the surgery. The nursing assessment should complement the surgeon's and anaesthesiologist's physical examination (Barnes, 2002).

General Survey. You should observe the patient's general appearance. Gestures and body movements may reflect weakness caused by illness. The patient may appear malnourished. Height, body weight, and history of recent weight loss are important indicators of nutritional status.

Preoperative vital signs, including blood pressure while sitting and standing, provide important baseline data with which alterations that occur during and after surgery can be compared. Some institutions request that blood pressure be obtained in both arms for comparison. Anxiety and fear commonly cause elevations in heart rate and blood pressure. As the effects of the anaesthesia diminish after surgery, compare vital sign findings with the preoperative baseline. Preoperative assessment of vital signs is also important to rule out fluid and electrolyte abnormalities (see Chapter 30).

An elevated temperature before surgery is a cause for concern. If the patient has an underlying infection, the surgeon may choose to postpone surgery until the infection has been treated. An elevated body temperature increases the risk for fluid and electrolyte imbalances after surgery.

Head and Neck. The condition of oral mucous membranes is one indicator of the patient's level of hydration. A dehydrated patient is at risk for developing serious fluid and electrolyte imbalances during surgery. Inspection of the soft palate and nasal sinuses can reveal sinus drainage, indicative of respiratory or sinus infection. Cervical lymph node enlargement may reveal local or systemic infection.

You should inspect the jugular veins for distension. Excess fluid within the circulatory system or failure of the heart to contract efficiently may lead to jugular vein distension and reveal a risk for cardiovascular complications during surgery.

During the examination of the oral mucosa, loose or capped teeth must be identified because they could become dislodged during endotracheal intubation. Dentures must be noted so that they can be removed before surgery, especially if general anaesthesia is required.

Integument. You should carefully inspect the skin, especially over bony prominences, such as the heels, elbows,

sacrum, and scapula. During surgery, a patient must lie in a fixed position, often for several hours. As a result, the patient may have an increased risk for pressure ulcers (see Chapter 46), especially if the skin is thin and dry and has poor turgor (Schoonhoven et al., 2002). Chronic use of steroids also increases the patient's susceptibility to skin tears. In addition, the overall condition of the skin reveals the patient's level of hydration. An older adult is at high risk for alteration in skin integrity from positioning on the OR table, causing pressure.

Thorax and Lungs. Assessment of the patient's breathing pattern and chest excursion aids in assessing ventilatory capacity. A decline in ventilatory function places the patient at risk for respiratory complications. For example, a patient who has high abdominal surgery will have difficulty breathing deeply because of a painful abdominal incision. Auscultation of breath sounds will indicate whether the patient has pulmonary congestion or narrowing of airways.

Existing atelectasis or moisture in the airways will be aggravated during surgery. Serious pulmonary congestion may cause postponement of the surgery. Certain anaesthetics can cause laryngeal muscle spasm; thus, if you auscultate wheezing in the airways preoperatively, the patient is at risk for further airway narrowing during surgery and after extubation (removal of the endotracheal tube); therefore, the physician should be made aware of these findings.

Heart and Vascular System. You should assess the character of the apical, radial, and peripheral pulses; the capillary refill; and the colour and temperature of the patient's extremities. If peripheral pulses are not palpable, a Doppler instrument should be used to assess their presence. Acceptable capillary refill occurs in less than three seconds. Measurement of capillary refill and assessment of peripheral pulses are particularly important for the patient having vascular surgery or orthopedic surgery (see Chapter 31).

Abdomen. You should assess the abdomen for size, shape, symmetry, and presence of distension. Assessment of preoperative bowel sounds is useful as a baseline. You also should ask whether the patient has regular bowel movements and inquire about the colour and consistency of stools.

Neurological Status. Preoperative assessment of neurological status is imperative for all patients who will be receiving general anaesthesia. The baseline neurological status assists with the assessment of ascent from anaesthesia. During the health history and physical assessment, observe the patient's level of orientation, alertness, and mood, noting whether the patient answers questions appropriately and can recall recent and past events. A patient who will have surgery for neurological disease (e.g., brain tumour or aneurysm) may demonstrate an impaired level of consciousness or altered behaviour.

If the patient is scheduled for spinal anaesthesia, preoperative assessment of gross motor function and strength is important. Spinal anaesthesia causes temporary paralysis of the lower extremities. You should be aware if a patient enters surgery with weakness or impaired mobility of the lower extremities so that, when the spinal anaesthetic wears off, you will not expect full motor function to return.

Diagnostic Screening

Before a patient has surgery, the surgeon may order diagnostic tests as determined by the patient's history and physical assessment. Table 48-6 lists common diagnostic tests performed preoperatively based on the patient's medical history.

The tests ordered are also determined by the procedure itself. For procedures where blood loss is expected (e.g., hip and knee replacements), a type and cross-match would be indicated preoperatively. The surgeon will designate the number of blood units to have available during surgery. Table 48-7 outlines the purpose and normal values for the more common blood tests. If diagnostic tests reveal severe problems, the surgeon may cancel surgery until the condition stabilizes. You are responsible for the preparation of patients for diagnostic studies and for coordinating completion of the tests. You also review diagnostic results as they become available, not only to alert physicians to these findings and to assist with planning appropriate therapy, but also to integrate these findings into your decisions related to patient care.

If a patient is over age 65 or has heart disease, an electrocardiogram (ECG) is usually mandatory. The ECG measures the electrical activity of the heart to assess the heart rate, rhythm, and other factors. A chest X-ray (an examination of the condition of the heart and lungs) is required for thoracic surgery or if the patient has certain medical conditions.

Pulmonary function testing and arterial blood gas analysis may be performed on patients with preexisting lung disease.

► TABLE 48-6

Common Diagnostic Tests Performed Preoperatively Based on Patient History

History	Tests
Hepatic disease	International normalized ratio (INR); partial thromboplastin time (PTT); liver enzymes, such as serum aspartate aminotransferase; alkaline phosphatase
Cardiovascular disease	blood urea nitrogen (BUN), creatinine, complete blood count (CBC), chest X-ray, electrocardiogram (ECG)
Pulmonary disease	CBC, chest X-ray, ECG
Central nervous system disease	White blood cell (WBC) count, electrolytes, BUN, creatinine, glucose, and electroencephalography (EEG)
Medications	
Diuretics	Electrolytes, and perhaps BUN and creatinine
Steroids	Electrolytes, glucose
Anticoagulants	INR, PTT

► TABLE 48-7 Diagnostic Screening for Surgical Patients

Measurement and Normal Values

Complete Blood Count (CBC)

Red blood cells (RBCs): Men: $4.7\text{--}5.14 \times 10^{12}/\text{L}$; Women: $4.2\text{--}4.87 \times 10^{12}/\text{L}$

Hemoglobin (Hgb): Men: 132–173 g/L; Women: 117–155 g/L

Hematocrit (Hct): Men: 0.43–0.49; Women: 0.38–0.44

White blood cells (WBCs): Adults and children >2 years: $4.5\text{--}11 \times 10^9/\text{L}$

Serum Electrolytes

Sodium (Na): 136–145 mmol/L

Potassium (K): 3.5–5.0 mmol/L

Chloride (Cl): 98–106 mmol/L

Bicarbonate (HCO_3): 22–26 mmol/L

Coagulation Studies

International normalized ratio (INR): 0.76–1.27 Activated partial thromboplastin time (APTT): 30–40 seconds Platelets: $150\text{--}400 \times 10^9$

Serum Creatinine

Men: 53–106 mcml/L

Women: 44–97 mcml/L

Blood Urea Nitrogen (BUN)

2.9–7.5 mmol/L

Glucose

Fasting: 4.2–6.1 mmol/L

Interpretation

Peripheral venous sample of blood measures RBCs, WBCs, Hgb, and Hct. May reveal infection, low blood volume, and potential for oxygenation problems. Surgeon may order blood replacement.

Peripheral venous sample of blood reveals significant fluid and electrolyte imbalances preoperatively. Attention is given to Na, K, and Cl levels. Intravenous (IV) fluid replacement may be indicated preoperatively.

INR, APTT, and platelet counts reveal clotting ability of blood. Reveals patients at risk for bleeding tendencies and thrombus formation.

Ability of kidneys to excrete creatinine, a by-product of muscle metabolism, indicates renal function. Elevated level can indicate renal failure.

Ability of kidneys to excrete urea and nitrogen indicates renal function. BUN becomes elevated if patient is dehydrated. Preoperative IV fluid replacement may be needed.

Finger stick or peripheral blood sample. Patients may require treatment of low or high levels preoperatively and postoperatively. Elevated blood sugar results from a deficiency in insulin secretion (type 1 diabetes), insulin action, or combination of both (type 2 diabetes).

Blood glucose levels and perhaps glycated hemoglobin (HbA1c) are measured on patients with diabetes.

Autologous infusions are an option for some patients who choose to donate their own blood before surgery. Although Canadian Blood Services screens all blood donors and blood products for infections such as HIV and hepatitis, some patients are more comfortable donating their own blood. The donation usually must be made several weeks before the scheduled surgery. Because of the short time frame now from preadmission to day of surgery, autologous infusions are used less as there is usually not even time for the process to be completed. The patient who does self-donate may exhibit lower hemoglobin and hematocrit levels on the day of surgery. Autotransfusion via the use of a cell-saver device during surgery may be possible if physicians anticipate large blood loss (e.g., open heart surgery). The cell-saver device, although expensive, returns washed RBCs to the patient and has created positive outcomes with regard to length of patient stay (Rothrock, 2003).

❖ Nursing Diagnosis

You will cluster patterns of defining characteristics gathered during assessment to identify nursing diagnoses for the surgical patient (Box 48-3). The patient with preexisting health problems is likely to have a variety of risk diagnoses. For example, a patient with preexisting bronchitis who has abnormal breath sounds and a productive cough will be at risk for ineffective airway clearance. In addition, a patient who undergoes a surgical procedure is at risk for developing infection at the surgical site, the IV site, or the bloodstream (sepsis). A diagnosis of risk for infection will require your attention from admission through convalescence.

The related factors for each diagnosis establish directions for nursing care that will be provided during one or all of the surgical phases. For example, the diagnosis of risk for infection related to an invasive procedure will require different interventions than if the related factor were inadequate immune response. Preoperative nursing diagnoses allow the nurse to

take precautions and actions so that the care provided during the intraoperative and postoperative phases is consistent with the patient's needs.

Nursing diagnoses made preoperatively will also focus on the potential risks a patient may face after surgery. Preventive care is essential so that the surgical patient can be managed effectively. The following are common nursing diagnoses relevant to the surgical patient:

- *Ineffective airway clearance*
- *Risk for allergy response to latex*
- *Anxiety*
- *Disturbed body image*
- *Risk for ineffective thermoregulation*
- *Ineffective breathing pattern*
- *Ineffective coping*
- *Fear*
- *Risk for deficient fluid volume*
- *Risk for infection*
- *Risk for perioperative-positioning injury*
- *Deficient knowledge (specify)*
- *Impaired physical mobility*
- *Acute pain*
- *Powerlessness*
- *Impaired skin integrity*
- *Disturbed sleep pattern*
- *Delayed surgical recovery*

❖ Planning

During planning, you once again synthesize information from multiple resources (Figure 48-2). For example, knowledge pertaining to adult learning principles, coupled with the patient's unique needs, will ensure a well-designed **preoperative teaching plan**. Critical thinking ensures that the patient's care plan integrates your knowledge, previous experience, and established standards of care. Previous experience in caring for surgical patients helps you anticipate how to approach patient care (e.g., complications to prevent and anticipate, and methods to reduce anxiety). Professional standards are especially important to consider when you develop a care plan, as they often provide a scientific basis for selecting effective nursing interventions. You will develop an individualized care plan for each nursing diagnosis (Box 48-4). You and the patient will set realistic expectations for care.

Successful planning requires the involvement of both the surgical patient and the family in establishing the care plan. Early patient involvement minimizes surgical risks and postoperative complications. A patient who is well informed about the surgical experience is less likely to be fearful and can prepare to participate in the postoperative recovery phase so that outcomes can be met. Diagnosis, interventions, and outcomes are established to ensure recovery or maintenance of the preoperative state.

Goals and Outcomes

The preoperative care plan is based on individualized nursing diagnoses. This plan is reviewed and modified during the intraoperative and postoperative periods. Outcomes established for each goal of care provide measurable behavioural evidence to gauge the patient's progress toward meeting the stated goals.

The following example provides a goal of care and expected outcomes relevant for the preoperative surgical patient:

► BOX 48-3 NURSING DIAGNOSTIC PROCESS (ACKLEY & LADWIG, 2011)

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Ask patient to describe previous surgical experiences.	Patient mentions a traumatic prior experience with surgery	<i>Fear related to knowledge deficit and previous surgical experience</i>
Ask patient about preoperative education and preparation before admission.	Unaware of preoperative testing	
Observe patient's nonverbal behaviour.	Patient's behaviour indicates fear and tension	
Assess vital signs.	Increased heart rate	

Figure 48-2 Critical thinking model for surgical patient planning.

- Patient is able to verbalize the significance of postoperative exercises.
- Patient verbalizes prevention of lung congestion and pneumonia as reasons for deep breathing and coughing exercises. Incentive spirometer to facilitate lung expansion is used less routinely now (Fanning, 2004). More recently, Agostini & Singh (2009) conducted a review of the literature examining the use of incentive spirometry following thoracic surgery. Postoperative physiotherapy regimes with or without incentive spirometry appeared to be effective following thoracic surgery, compared to no physiotherapy. However, the authors stressed that further studies need to be done in this area.
- Patient verbalizes promotion of blood flow to prevent leg clots as reason for postoperative leg exercises.
- Patient verbalizes rationale for early ambulation, as it improves lung function, assists with return of bowel function, and promotes recovery.

Setting Priorities

Using clinical judgement, you should prioritize nursing diagnoses and interventions based on the assessed unique needs of each patient. Patients who need emergency surgery may experience changes in their physiological status that require the nurse to reprioritize quickly. For example, if a patient's blood pressure begins to drop, hemodynamic stabilization becomes a priority over education and stress management. Generally, when the preoperative situation is more controlled, the approach to each patient must be thorough and reflect an understanding of the implications of the patient's age, physical and psychological health, educational level, and cultural and religious practices. Increasingly, patients are preparing advanced medical directives to indicate their wishes should unexpected aggressive medical treatment be required after surgery.

► BOX 48-4 NURSING CARE PLAN

Deficient Knowledge Regarding Preoperative and Postoperative Care Requirements

Assessment

Mrs. Campana is an 80-year-old woman scheduled to be admitted in five days for elective bowel resection. Joe Marrero is the nurse in the clinic surgery service assigned to prepare Mrs. Campana for surgery. During his initial discussion with Mrs. Campana, Joe observes her to be alert and oriented. Mrs. Campana has severely reduced visual acuity but is able to hear Joe's questions clearly.

Assessment Activities

Ask Mrs. Campana about previous surgeries and her experience with them.

Ask Mrs. Campana what she has been told regarding her surgery.

Ask Mrs. Campana what she has been told regarding preoperative preparation and what to expect postoperatively.

Findings and Defining Characteristics

She responds, "I had surgery over 20 years ago, and I was in the hospital for 10 days."

She states that her surgeon explained the procedure using a drawing of the bowel and indicating the location of the part to be removed.

She states that she received information from the surgeon's office regarding medicines to stop taking and those she should take on the morning of surgery, her diet before surgery and when to stop eating, and who to call with questions. She does not recall receiving information regarding what to expect postoperatively.

Continued

► BOX 48-4 NURSING CARE PLAN—cont'd

Assessment Activities

Assess Mrs. Campana's ability to read typical font type.

Assess Mrs. Campana's family and support system for preoperative and postoperative assistance.

Findings and Defining Characteristics

She is unable to read the text font on the newspaper; she can read the headlines with her glasses.

She states that her daughter will be coming into town on the day of surgery to help her after surgery.

Nursing Diagnosis: Deficient knowledge regarding preoperative and postoperative care requirements related to lack of exposure to information.

Planning

Goals (Nursing Outcomes Classification)*

Patient will understand the postoperative routines of surgical care by day before surgery.

Patient will participate actively in postoperative recovery activities by day 1 after surgery.

Expected Outcomes

Knowledge of Treatment Procedures

Patient will discuss monitoring routines after surgery by morning of surgery in the preoperative period.

Patient will be able to describe importance of postoperative exercises by morning of surgery, including turn, cough, and deep breathing; incentive spirometer; leg exercises.

Patient will be able to describe schedule for activity and nutritional management postoperatively by day 1 after surgery.

Patient will successfully perform postoperative exercises by morning of surgery in the preoperative period.

*Outcome classification labels from Moorhead, S., Johnson, M., & Maas, M. L. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]

Teaching in the Preoperative Period

Provide patient with audiotape program that explains preoperative and postoperative routines. Supply instruction booklet designed for the visually impaired. Make a follow-up call to patient and to her daughter to give them an opportunity to ask questions and voice concerns. Document all phases of education—preoperative before admission, day of surgery, and postoperative—provided to patient in her record.

On admission to hospital, demonstrate to patient and daughter the performance of postoperative exercises and how to get out of bed.

Explain sensations to be expected postoperatively (e.g., incisional pain that will be controlled with medications, intravenous [IV], nasogastric tube, wound care, frequent vital signs assessments).

Give patient opportunity to return demonstrate postoperative exercises before surgery.

Correct any unrealistic expectations the patient or daughter may have regarding surgery.

Rationale

Preadmission education can require less teaching time and better performance of exercises on admission. Education has a beneficial effect in reducing postoperative anxiety (Shuldhham, 1999).

Demonstration is an effective method to reinforce didactic instruction.

Teaching about sensory aspects (what the patient sees, feels, smells) should be structured (Shuldhham, 1999).

Return demonstration measures patient learning and provides an opportunity to reinforce instruction.

Unrealistic expectations, when unmet, can contribute to patient's anxiety. Psychological preparation for surgery reduces anxiety.

[†]Intervention classification labels from Dochterman, J. M., Bulechek, G. M., & Butcher, H. K. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Ask patient to describe typical monitoring and care activities after surgery. Document evaluation of patient's understanding and demonstration of learned activities in patient's record.

Patient Response and Finding

She is able to verbalize typical monitoring and care after surgery. She states that the instruction booklet and audiotape were both helpful.

Achievement of Outcome

Mrs. Campana has a good understanding of the typical postoperative course.

► BOX 48-4 NURSING CARE PLAN—cont'd

Nursing Actions	Patient Response and Finding	Achievement of Outcome
Observe patient's demonstration of postoperative exercises.	She is able to demonstrate leg exercises and deep breathing and coughing exercises but is having difficulty with incentive spirometer use.	Mrs. Campana is able to demonstrate most of the postoperative exercises but needs further teaching and practice on incentive spirometer use.
Explore with patient and daughter if they have any remaining fears or concerns.	Both Mrs. Campana and her daughter deny any fears or concerns at the present time.	Informational and psychological needs of Mrs. Campana and her daughter have been met.

❖ Implementation

Preoperative nursing interventions provide the patient with an understanding of the surgery and prepare the patient not only physically and psychologically for surgical intervention but also to be an active participant in the recovery process.

Informed Consent

Surgery cannot be legally or ethically performed until a patient understands the need for a procedure, the steps involved, the risks, the expected results, and alternative treatments. The surgeon is responsible for explaining the procedure and obtaining the **informed consent**. Often today, the consent is signed in the physician's office or in the preadmission unit. If, as a nurse, you are involved in obtaining the signature, you must ensure before signing that the patient understands the procedure. If the patient is unclear about the procedure, the consent should not be signed and the physician should be notified (see Chapter 8).

Preoperative Teaching

Education is an important aspect of the patient's surgical experience. Preoperative teaching reflects a patient's expected postoperative recovery. This teaching has a positive influence on the patient's recovery. For example, Oetker-Black et al. (2003) found that an efficacy-enhancing teaching protocol for patients post-hysterectomy enhanced ambulation postoperatively. Nurses in preadmission clinics may call patients up to one week before surgery to answer the patient's questions and reinforce explanations. Preoperative information and instructions may include telephone calls, mailings from the physician's office or hospital, preoperative teaching guidelines and checklists, and the use of videotapes or **clinical pathways** (Figure 48-3).

Pritchard (2011) discussed the importance of giving appropriate information to patients preoperatively. Information needs to be tailored to address patients' individual needs (Suhonen & Leino-Kilpi, 2006). This targeted information, then, is meaningful to the patient. Carr et al. (2005), in a study of women having major gynecological surgery, examined the women for anxiety, depression, and pain after surgery. They concluded that patients, especially those who are particularly anxious, can benefit from specific information prior to surgery, such as their length of stay or what their pain will be like. Pritchard (2011) suggests that the use of standard information sheets such as preoperative information sheets is not sufficient to address patients' information needs or reduce their preoperative anxiety.

Including family members in preoperative preparation is advised. Family members need to be aware of the normal expectations after discharge from hospital. They also may

recognize untoward events that may unfold once the patient is home. If anxious relatives do not understand routine postoperative events, their anxiety will likely heighten the patient's fears and concerns. Preoperative preparation of family members can help to minimize anxiety and misunderstanding.

You should provide patients with information about sensations typically experienced after surgery. Preparatory information helps patients anticipate the steps of a procedure and thus helps them form realistic images of the surgical experience. When events occur as predicted, patients are better able to cope and attend to them. For example, in the OR, the anesthesiologist may apply ointment to patients' eyes to prevent corneal damage. Warning patients about sensations of blurred vision will reduce their anxiety on awakening from surgery. Sensations that you may describe include expected pain at the surgical site, tightness of dressings, dryness of the mouth, or a sore throat resulting from an endotracheal tube.

Anxiety and fear are barriers to learning, and both emotions are heightened as surgery approaches. You should assess the surgical patient's readiness and ability to learn. If the patient is capable of and receptive to learning, present information in a logical sequence, beginning with preoperative events and advancing to intraoperative and postoperative routines. The following demonstrates a patient's understanding of the surgical experience.

Patient Cites Reasons for Preoperative Instructions and Exercises. If given a rationale for preoperative and postoperative procedures, the patient is better prepared to participate in his or her care. Every preoperative teaching program includes explanation and demonstration of postoperative exercises: diaphragmatic breathing, coughing, turning, and leg exercises. These exercises are designed to prevent postoperative complications (Skill 48-1). Remember that physiotherapists, as part of the interprofessional team, can facilitate patient mobility postoperatively.

If the patient is measured for elastic stockings or sequential compression devices, you must teach about the purpose of these devices and the nursing care that will be required after their application (see Chapter 45).

After explaining each exercise, you should demonstrate it. You act as a coach, guiding the patient through each exercise. For example, you assess whether the patient is sitting properly and help the patient place his or her hands in the proper position during breathing. You then allow the patient time for independent practice and return to evaluate effectiveness before surgery.

Patient States the Time of Surgery. The patient and family should be told the approximate time that surgery will begin. If the hospital has a busy OR schedule, it is best to let them know whether other procedures are scheduled before the

► SKILL 48-1 Demonstrating Postoperative Exercises

**Delegation Considerations**

The skill of demonstrating postoperative exercises should not be delegated to unregulated care providers (UCPs). However, other aspects of patient care may be delegated. When using UCPs be sure to do the following:

- Educate the UCP to encourage patients to practise exercises regularly, following instruction.
- Instruct the UCP to inform you if patients are unwilling to perform these exercises.

Equipment

- Pillow or wrapped blanket (used to splint surgical incision during coughing)
- Incentive spirometry may be used less routinely now (Fanning, 2004)
- Positive expiratory pressure (PEP) device

Procedure**STEPS**

1. Assess the patient's risk for postoperative respiratory complications. Review the medical history to identify presence of chronic pulmonary conditions (e.g., emphysema, chronic bronchitis, asthma), any condition that affects chest wall movement, history of smoking, and presence of reduced hemoglobin.
2. Assess ability to cough and breathe deeply by having the patient take a deep breath and observing movement of shoulders and chest wall. Measure chest excursion during deep breath. Ask patient to cough after taking deep breath.
3. Assess risk for postoperative thrombus formation. (Older patients, those with active cancer, and those immobilized for more than three days are most at risk.) Observe for localized tenderness along the distribution of the venous system, swollen calf or thigh, calf swelling more than 3 cm compared with asymptomatic leg, pitting edema in symptomatic leg, and collateral superficial veins. If any of these signs are present, notify the physician.

RATIONALE

- General anaesthesia predisposes the patient to respiratory problems because the lungs are not fully inflated during surgery and the cough reflex is suppressed, so that mucus collects within airway passages. After surgery, the patient may have reduced lung volume and require greater efforts to cough and breathe deeply; inadequate lung expansion can lead to atelectasis and pneumonia. The patient is at greater risk for developing respiratory complications if other chronic lung conditions are present. Smoking damages ciliary clearance and increases mucous secretion. Reduced hemoglobin level can lead to inadequate oxygenation.
- Reveals maximum potential for chest expansion and ability to cough forcefully; serves as baseline to measure ability to perform exercises after surgery.
- Venous stasis, decreased perfusion, and vein trauma exist simultaneously for thrombus formation to occur (Lewis et al., 2010). After general anaesthesia, circulation is slowed, thus increasing the risk for clot formation. Immobilization results in decreased muscular contraction in the lower extremities, which promotes venous stasis.

Critical Decision Point: A positive Homans' sign (calf pain when dorsiflexing the patient's foot with knee flexed) has been found to have a low specificity for deep vein thrombosis (DVT) diagnosis and often is not present or may be present when no DVT exists (Anand et al., 1998; Tick et al., 2002).

4. Assess the patient's ability to move independently while in bed.
5. Explain postoperative exercises to the patient, including their importance to recovery and physiological benefits.
6. Demonstrate exercises.
 - A. **Diaphragmatic breathing**
 - (1) Assist the patient to a comfortable sitting position on side of bed or in chair or to standing position.
 - (2) Stand or sit facing the patient.

- Determines existence of any mobility restrictions.
- Information allows the patient to understand the significance of exercises and can motivate learning. People tend to learn new skills when benefits can be gained.
- Upright position facilitates diaphragmatic excursion.
- Allows the patient to observe the breathing exercise.

Continued

► SKILL 48-1 Demonstrating Postoperative Exercises—cont'd

video

- (3) Instruct the patient to place palms of hands across from each other, down and along lower borders of anterior rib cage. Place tips of third fingers lightly together (see Step 6A[3] illustration). Demonstrate for the patient.

Step 6A(3) Deep breathing exercise—placement of hands on upper abdomen during inhalation.

- Position of hands allows the patient to feel movement of the chest and abdomen as the diaphragm descends and lungs expand.
- (4) Have the patient take slow, deep breaths, inhaling through the nose and pushing abdomen against hands. Tell the patient to feel the middle fingers separate during inhalation. Demonstrate.
 - (5) Explain that the patient will feel normal downward movement of the diaphragm during inspiration. Explain that abdominal organs descend and the chest wall expands.
 - (6) Avoid using auxiliary chest and shoulder muscles while inhaling and instruct the patient in same manner.
 - (7) Have the patient hold a slow, deep breath for a count of three and then slowly exhale through the mouth as if blowing out a candle (with pursed lips). Tell the patient that middle fingertips will touch as the chest wall contracts.
 - (8) Repeat breathing exercise three to five times.
 - (9) Have the patient practise the exercise. Instruct the patient to take 10 slow, deep breaths every hour while awake during the postoperative period until mobile.
- B. Incentive spirometry** (may be used less routinely now)
- (1) Perform hand hygiene.
 - (2) Instruct the patient to assume semi-Fowler's or high-Fowler's position.
 - (3) Either set or indicate to the patient on the device scale the volume level to be attained with each breath.
 - (4) Demonstrate to the patient how to place the mouthpiece of the spirometer so that the lips completely cover it (see Step 6B[4] illustration).
- Taking slow, deep breaths prevents panting or hyperventilation. Inhaling through the nose warms, humidifies, and filters air.
 - Explanation and demonstration focus on normal ventilatory movement of the chest wall. The patient develops understanding of how diaphragmatic breathing feels.
 - Using auxiliary chest and shoulder muscles increases useless energy expenditure.
 - Allows for gradual expulsion of all air and helps prevent airway collapse by facilitating the maintenance of positive airway pressure.
 - Allows the patient to observe a slow, rhythmic breathing pattern.
 - Repetition of the exercise reinforces learning. Regular deep breathing prevents postoperative complications.
 - Reduces transmission of microorganisms.
 - Promotes optimal lung expansion during respiratory manoeuvre.
 - Establishes goal of the volume level necessary for lung expansion.
 - The higher the setting, the more effort will be required by the patient. Ideally it should deliver a pressure range of 10–20 cm H₂O during passive expiration (American Association for Respiratory Care [AARC], 2002)

► SKILL 48-1 Demonstrating Postoperative Exercises—cont'd

video

- (5) Instruct the patient to inhale slowly and maintain constant flow through the unit, attempting to reach goal volume. When maximal inspiration is reached, the patient should hold breath for two to three seconds (see Step 6B[5] illustration) and then exhale slowly. Number of breaths should not exceed 10 to 12 per minute in each session.

Step 6B(4) Patient inhales using incentive spirometer.

- (6) Instruct the patient to breathe normally for a short period.
 (7) Have the patient repeat the manoeuvre until goals are achieved.
 (8) Perform hand hygiene.

C. Positive expiratory pressure (PEP) therapy and "huff" coughing

- (1) Perform hand hygiene.
 (2) Set PEP device to the setting ordered.
- (3) Instruct the patient to assume semi-Fowler's or high-Fowler's position and place nose clip on the patient's nose (see Step 6C[3] illustration).

Step 6C(3) Positive expiratory pressure device. **Source:** Perry, A. G., & Potter, P. A. (2010). Preoperative and postoperative care. In A. G. Perry & P. A. Potter, *Clinical nursing skills and techniques* (7th ed., p. 951). St Louis, MO: Elsevier.

- (4) Have the patient place lips around the mouthpiece. The patient should take a full breath and then exhale two to three times longer than inhalation. Pattern should be repeated for 10 to 20 breaths.
 (5) Remove device from the mouth and have the patient take a slow, deep breath and hold for three seconds.

- Maintains maximal inspiration and reduces risk of progressive collapse of individual alveoli. Slow breath prevents or minimizes pain from sudden pressure changes in chest.

Step 6B(5) Incentive spirometer increases flow of air into lungs.

- Prevents hyperventilation and fatigue.
- Ensures correct use of spirometer.
- Reduces transmission of microorganisms.
- Reduces transmission of microorganisms.
- The higher the setting, the more effort will be required by the patient. Ideally, the device should deliver 10 to 20 cm of water during passive expiration (American Association for Respiratory Care [AARC], 2002).
- Promotes optimal lung expansion and expectoration of mucus (AARC, 2002).

- Ensures that all breathing is done through the mouth and that the device is used properly.
- Promotes lung expansion before coughing.

Continued

► SKILL 48-1 Demonstrating Postoperative Exercises—cont'd

- (6) Instruct the patient to exhale in quick, short, forced exhalations or “huffs.”

D. Controlled coughing

- (1) Explain the importance of maintaining an upright position.
 - (2) Demonstrate coughing. Take two slow, deep breaths, inhaling through the nose and exhaling through the mouth.
 - (3) Inhale deeply a third time and hold breath to count of three. Cough fully for two or three consecutive coughs without inhaling between coughs. (Tell the patient to push all air out of lungs.)
- “Huff” coughing, or forced expiratory technique, promotes bronchial hygiene through increased expectoration of secretions.
 - Position facilitates diaphragm excursion and enhances thorax expansion.
 - Deep breaths expand the lungs fully so that air moves behind mucus and facilitates the effects of coughing.
 - Consecutive coughs help remove mucus more effectively and completely than one forceful cough.

Critical Decision Point: Coughing may be contraindicated after brain or eye surgery.

- (4) Caution the patient against simply clearing the throat instead of coughing. Explain that coughing will not cause injury to incision when done correctly.
 - (5) If surgical incision will be abdominal or thoracic, teach the patient to place one hand over the incisional area and the other hand on top of it. During breathing and coughing exercises, the patient presses gently against the incisional area to splint or support it. A pillow over the incision is optional (see Step 6D[5] illustration).
- Clearing the throat does not remove mucus from deep in airways. Postoperative incisional pain makes it harder for the patient to cough effectively.
 - Surgical incision cuts through muscles, tissues, and nerve endings. Deep breathing and coughing exercises place additional stress on the suture line and cause discomfort.
 - Splinting the incision with hands provides firm support and reduces incisional pulling. (Some patients prefer to have a pillow to place over the incision.)

Step 6D(5) Techniques for splinting incision. **Source:** Lewis, S. M., Heitkemper, M. M., Dirksen, S. R., O'Brien, P. G., Bucher, L., Barry, M. A., Goldsworthy, S., & Goodridge, D. (2010). *Medical-surgical nursing: Assessment and management of clinical problems* (2nd Canadian ed., p. 437). Toronto: Elsevier.

- (6) The patient continues to practise coughing exercises, splinting imaginary incision. Instruct the patient to cough two to three times every two hours while awake.
 - (7) Instruct the patient to examine sputum for consistency, odour, amount, and colour changes.
- Value of deep coughing with splinting is stressed to expectorate mucus effectively with minimal discomfort.
 - Sputum consistency, odour, amount, and colour changes may indicate presence of pulmonary complication, such as pneumonia.

E. Turning

- (1) Instruct the patient to assume supine position and move to side of bed if permitted by surgery. Have the patient move by bending knees and pressing heels against the mattress to raise and move buttocks (see Step 6E[1] illustration). Top side rails on both sides of the bed should be raised.
 - (2) Instruct the patient to place right hand over the incisional area to splint it.
 - (3) Instruct the patient to keep right leg straight and flex left knee up (see Step 6E[3] illustration). If back or vascular surgery is being performed, patient will need to logroll or will require assistance with turning.
- Positioning begins on side of the bed so that turning to other side will not cause the patient to roll toward the bed's edge.
 - Supports and minimizes pulling on the suture line during turning.
 - Straight leg stabilizes the patient's position. Flexed left leg shifts weight for easier turning.

Step 6E(1) Buttocks lift.

Step 6E(3) Leg position for turning.

► SKILL 48-1 Demonstrating Postoperative Exercises—cont'd

- (4) Have the patient grab the right side rail with left hand, pull toward right, and roll onto right side.
- (5) Instruct the patient to turn every two hours while awake.

F. Leg exercises

- (1) Have the patient assume supine position in bed. Demonstrate leg exercises by performing passive range-of-motion exercises and simultaneously explaining exercise.
- (2) Rotate each ankle in complete circle. Instruct the patient to draw imaginary circles with big toe (see Step 6F[2] illustration). Repeat five times.

- Pulling toward side rail reduces effort needed for turning.
- Reduces risk of vascular and pulmonary complications.
- Provides normal anatomical position of lower extremities.
- Leg exercises maintain joint mobility and promote venous return to prevent thrombi.

Desirable
Foot circles

Step 6F(2) Foot circles. **Source:** Lewis, S. M., Heitkemper, M. M., Dirksen, S. R., O'Brien, P. G., Bucher, L., Barry, M. A., Goldsworthy, S., & Goodridge, D. (2010). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (2nd Canadian ed., p. 439). Toronto: Elsevier.

- (3) Alternate dorsiflexion and plantar flexion of both feet. Direct the patient to feel calf muscles contract and relax alternately (see Step 6F[3] illustrations, parts A and B). Repeat five times.

- Stretches and contracts gastrocnemius muscles.

Essential
Alternate dorsiflexion and plantar flexion

Step 6F(3) A, Alternate dorsiflexion and plantar flexion. **B,** Patient pushes feet to perform plantar flexion. **Source:** Lewis, S. M., Heitkemper, M. M., Dirksen, S. R., O'Brien, P. G., Bucher, L., Barry, M. A., Goldsworthy, S., & Goodridge, D. (2010). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (2nd Canadian ed., p. 439). Toronto: Elsevier.

Continued

► SKILL 48-1 Demonstrating Postoperative Exercises—cont'd

video

- (4) Perform quadriceps setting by tightening thigh and bringing knee down toward mattress, then relaxing (see Step 6F[4] illustration). Repeat five times.
- (5) Have the patient alternately raise each leg straight up from the bed surface, keeping legs straight, and then have the patient bend leg at hip and knee (see Step 6F[5] illustration). Repeat five times.

Step 6F(4) Quadriceps (thigh) setting. **Source:** Lewis, S. M., Heitkemper, M. M., Dirksen, S. R., O'Brien, P. G., Bucher, L., Barry, M. A., Goldsworthy, S., & Goodridge, D. (2010). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (2nd Canadian ed., p. 439). Toronto: Elsevier.

7. Have the patient practise exercises at least every two hours while awake. Instruct the patient to coordinate turning and leg exercises with diaphragmatic breathing, incentive spirometry, and coughing exercises.
8. Observe the patient's ability to perform all five exercises independently.

Step 6F(5) Hip and knee movements. **Source:** Lewis, S. L., Heitkemper, M. M., Dirksen, S. R., O'Brien, P. G., Bucher, L., Barry, M. A., Goldsworthy, S., & Goodridge, D. (2010). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (2nd Canadian ed., p. 439). Toronto: Elsevier.

- Contracts muscles of upper legs, maintains knee mobility, and enhances venous return.
- Promotes contraction and relaxation of quadriceps muscles.
- Repetition of sequence reinforces learning. Establishes routine for exercises that develops habit for performance. Sequence of exercises should be leg exercises, turning, breathing, incentive spirometry, and coughing.
- Ensures that the patient has learned correct techniques. Documents the patient's education and provides data for instructional follow-up.

Unexpected Outcomes

Inability to perform exercises correctly after surgery

Unwillingness to perform exercises postoperatively because of incisional pain of thorax or abdomen (deep breathing, coughing, and turning) or because of surgery involving lower abdomen, groin, buttocks, or legs (leg exercises, turning)

Related Interventions

- Assess for the presence of anxiety, pain, and fatigue.
- Teach the patient stress reduction techniques, pain management strategies, or both.
- Repeat the teaching, using additional demonstration or redemonstration at a time when family members or friends are present.
- Instruct the patient to ask for pain medication 30 minutes before performing postoperative exercises or to use patient-controlled analgesia (PCA) immediately before exercising.
- Report to the surgeon inadequate pain relief and the need to change analgesic or increase dose.

Recording and Reporting

- Record the exercises demonstrated and whether the patient can perform them independently.
- Report any problems the patient has in practising exercises to the nurse assigned to the patient on the next shift for follow-up.

patient's. The surgeon usually informs the patient and family of the anticipated length of surgery. Unanticipated delays may occur for many reasons. The family needs to be aware that delays do not necessarily indicate a problem.

Patient Knows Where the Postoperative Unit Is and Where the Family Will Be During Surgery and Recovery. The unit to which the patient is admitted before surgery may be different from the postoperative unit. The family needs to know where the patient will be taken after surgery. You also should explain where the family can wait and where the surgeon will attempt to find family members after surgery. Many institutions have implemented programs in which the circulating nurse gives periodic reports to the family in the waiting room when prolonged surgeries are involved. If the patient will be taken to a special unit postoperatively, it helps to orient the patient and family members to the unit's environment before surgery. Programs designed to connect

with the family also have been developed in day-surgery areas (Andrews, 2009).

Patient Discusses Anticipated Postoperative Monitoring and Therapies. The patient and family need to know about postoperative events. If they understand the frequency of postoperative vital sign monitoring before surgery occurs, they will be less apprehensive when nurses measure vital signs. You can also explain whether the patient is likely to have IV lines, monitoring lines, dressings, or drainage tubes or whether he or she will require ventilator support.

Patient Describes Surgical Procedures and Postoperative Treatment. After the surgeon has explained the basic purpose of the surgical procedure, the patient may ask you additional questions to clarify any misunderstandings. Preestablished teaching standards, such as those integrated in clinical pathways for preoperative and postoperative care (Figure 48-4), give you an excellent guide for instruction. A

good starting point is to ask what the patient has been told. If the patient has limited understanding about the surgery, you can provide additional explanations. If necessary, the surgeon can be asked to re-inform the patient.

Patient Describes Postoperative Activity Resumption. The type of surgery a patient undergoes affects the speed with which normal physical activity and regular eating habits can be resumed. You should explain that it is normal to progress gradually in both activity and eating. If the patient tolerates activity and diet well, activity levels will progress more quickly.

Patient Describes Pain-Relief Measures. Typically, one of the surgical patient's fears is pain. The family is also concerned for the patient's comfort. Pain after surgery is expected. You should inform the patient and family of interventions available for pain relief (e.g., analgesics, positioning, splinting, and relaxation exercises; see Chapter 41). The patient needs to know the schedule for analgesic drugs, their route of administration, and their effects.

Surgical patients may avoid taking pain-relief drugs for fear of becoming dependent on them. You should encourage the patient to use analgesics as needed and explain to the patient that the risks of becoming dependent are minimal. Explain to the patient that unless the pain is controlled, it will be difficult for the patient to participate in postoperative therapy such as mobilization. The patient should be encouraged to inform you before the pain becomes a constant discomfort. If a patient waits until pain becomes excruciating, an analgesic may not provide relief at the dose ordered. Patients who will have patient-controlled analgesia (PCA) after surgery should be taught how to push the button when they begin to feel discomfort and should understand that use of PCA will not cause overmedication (see Chapter 41). The patient should also understand the length of time that it takes for the drug to begin working. Information from preoperative assessment will be helpful to you when teaching about pain-relief measures. Pain reporting and expectations regarding pain management based on a patient's cultural beliefs are areas that need to be explored both individually and systematically through research (Douglas, 1999; Ramer et al., 1999).

Patient Expresses Feelings Regarding Surgery. If the patient is admitted to hospital during the preoperative surgical phase, frequent visits by staff, diagnostic testing, and physical preparation for surgery consume a lot of time; as a result, the patient has few opportunities to reflect on the upcoming surgical experience. You must recognize the patient as a unique individual. The patient and family need time to express their feelings about the surgery. The patient's level of anxiety influences the frequency of discussions. While delivering bedside care, you can encourage expression of concerns. Family members may wish to discuss their concerns without the patient present so that their fears will not frighten the patient and vice versa. Establishing a trusting and therapeutic relationship with the patient and family allows this to happen.

Acute Care

Activities in the acute care setting during the preoperative phase focus on interventions to prepare the patient physically for surgery.

Physical Preparation. The degree of preoperative physical preparation depends on the patient's health status and on the surgery to be performed. A seriously ill patient receives more supportive care in the form of medications, IV

fluid therapy, and monitoring than does a patient facing a minor elective procedure. You should explain the purpose of all procedures.

Maintenance of Normal Fluid and Electrolyte Balances. The surgical patient is vulnerable to fluid and electrolyte imbalances as a result of inadequate preoperative intake, excessive fluid losses during surgery, and the physiological effect of third spacing (redistribution of intravascular fluid into interstitial space) in the initial postoperative period (see Chapter 39). A patient traditionally took nothing by mouth (NPO) after midnight on the morning of surgery to keep the stomach empty and thus reduce the risk of vomiting and aspiration. Recommendations for preoperative fasting have been published by the Canadian Anesthesiologists Society (2005) and by the American Society of Anesthesiologists (American Society of Anesthesiologists Task Force on Preoperative Fasting, 1999). They recommended fasting from intake of a light meal (e.g., toast and clear liquids) for six or more hours, and from clear liquids for two to three hours before elective procedures that require general anaesthesia, regional anaesthesia, or sedation.

Agencies vary as to the extent that these guidelines have been adopted. You will remove fluids and solid foods from the patient's bedside and post a sign over the patient's bed to alert hospital personnel and family members about fasting restrictions. The patient may be instructed to take specific medications (e.g., cardiovascular medications, anticonvulsants, or antibiotics) with a sip of water. Although the parameters of preoperative fasting have changed, studies demonstrate that recent guidelines have not been fully implemented and that multidisciplinary improvement processes may be required (O'Callaghan, 2002; Williams, 1999).

A patient who is at home on the evening before surgery must understand the importance of the specific fasting period that has been ordered. You can allow patients to rinse their mouths with water or mouthwash and brush their teeth immediately before surgery as long as they do not swallow water. You must notify the surgeon and anaesthesiologist if the patient has eaten or drunk fluids during the fasting period.

During surgery, normal mechanisms for controlling fluid and electrolyte balances, including respiration, digestion, circulation, and elimination, are disturbed. The surgical procedure may cause extensive losses of blood and other body fluids. The surgical stress response aggravates any fluid and electrolyte imbalances. The patient's preoperative diet should include foods high in protein, with sufficient carbohydrates, fat, and vitamins. If a patient cannot eat because of gastrointestinal alterations or impairments in consciousness, an IV route for fluid replacement is started. The physician assesses serum electrolyte levels to determine the type of IV fluids and electrolyte additives to administer. Patients with severe nutritional imbalances may require supplements containing concentrated protein and glucose (see Chapter 42).

Reduction of Risk of Surgical Wound Infection. The risk of developing a surgical wound infection is determined by the amount and type of microorganisms contaminating a wound, the susceptibility of the host, and the surgical wound itself. All three factors interact to cause infection. Antibiotics may be ordered in the preoperative period. Risk of wound infection decreases when an antibiotic is present in sufficient concentrations at the wound site before incision (Polk & Christmas, 2000). Antibiotics given before surgery may be administered orally or intravenously. Increasingly, antibiotics

are administered in the OR immediately before surgery (Dellinger et al., 1994).

Microorganisms grow and multiply on the skin. Without proper skin preparation, the risk of postoperative wound infection is high. Many surgeons instruct patients to bathe or shower the evening before surgery. Some physicians may request that patients bathe or shower more than once, whereas others may ask patients to give special attention to cleansing the proposed operative site. This attention could include the use of an antibacterial soap. Depending on the surgical procedure, a patient may also shower on the morning of surgery. If the surgical procedure involves the head, neck, or upper chest area, the patient may be required to shampoo his or her hair. Cleansing and trimming of fingernails and toenails also may be necessary.

The need for hair removal is less common now and depends on the amount of hair, the location of the incision, and the surgical procedure planned (AORN, 2002b). Hair removal can damage and cause breaks in the patient's skin, which may allow for the entry of microorganisms. If required, hair is removed with a clipper or shaver as close to the time of surgery as possible. Short hospital stays are known to reduce the chance of a nosocomial (hospital-acquired) infection. Respiratory, urinary tract, and wound infections can all be acquired during hospitalization. This is one advantage of ambulatory surgical procedures, because the patient usually returns home once the surgery has been completed.

Precautions for Patient Requiring Infection Control Procedures. If a patient requires surgery but also has an infectious process, the OR must be notified in advance to ensure appropriate preparation. For example, patients with tuberculosis would be placed in a reverse airflow OR suite and subsequently in a reverse airflow room in the postanesthesia care unit (PACU). Patients with methicillin-resistant *Staphylococcus aureus* (MRSA) may have their surgery performed at the end of the day so that the surgical suite can be cleaned afterward. These patients on transfer to the PACU are placed in an isolation room. Many hospitals now require that all "same-day admit" patients be screened for MRSA and vancomycin-resistant enterococci (VRE).

Prevention of Bowel and Bladder Incontinence. The patient may receive a bowel preparation (e.g., a cathartic or enema) if the surgery involves the lower gastrointestinal system or lower abdominal organs. Manipulation of portions of the gastrointestinal tract during surgery results in absence of peristalsis for 24 hours or longer. Enemas and cathartics, such as GoLYTELY, cleanse the gastrointestinal tract to prevent intraoperative incontinence and postoperative constipation. An empty bowel reduces the risk for injury to the intestines and minimizes contamination of the operative wound if a portion of the bowel is incised or opened accidentally, or if colon surgery is planned (see Chapter 44).

The bladder is not prepared until the morning of surgery.

Promotion of Rest and Comfort. Rest is essential for normal healing. Anxiety about the impending surgery can easily interfere with the patient's ability to relax or sleep. As well, the underlying condition requiring surgery may be painful, further impairing rest.

If the patient is admitted to hospital before the day of surgery, you should attempt to make the patient's environment quiet and comfortable. Sometimes the patient is ordered a sedative-hypnotic or anxiolytic agent for the night before surgery. Sedative-hypnotics (e.g., temazepam [Restoril]) affect

and promote sleep. Anxiolytic agents (e.g., alprazolam [Xanax]) act on the cerebral cortex and limbic system to relieve anxiety.

An advantage of ambulatory surgery or same-day surgical admissions is that the patient is able to sleep at home the night before surgery. He or she is likely to get more rest in a familiar environment. The nonhospitalized patient also may have medication ordered by the physician if apprehension about surgery interferes with a good night's rest.

Preparation on the Day of Surgery. You must complete a number of interventions before releasing the patient for surgery.

Hygiene. Basic hygiene measures provide additional comfort before surgery. The patient may want to bathe before surgery. Because the patient cannot wear personal nightwear to the OR, you must provide a clean hospital gown. If the patient has been NPO for the last several hours, his or her mouth may be very dry. You may offer the patient mouthwash and toothpaste, again with the caution not to swallow any water.

Hair and Cosmetics. During surgery with general anesthesia, the patient's head is positioned to introduce an endotracheal tube into the airway (see Chapter 38). This procedure may involve manipulation of the patient's hair and scalp. To avoid injury, ask the patient to remove hairpins or clips before leaving for surgery. Hairpieces or wigs also should be removed. Long hair can be braided. The patient will wear a disposable hat before entering the OR.

During and after surgery, the anaesthesiologist and nurses will assess skin and mucous membranes to determine the patient's level of oxygenation and circulation. Therefore, all makeup (lipstick, powder, blush, nail polish) should be removed to expose normal skin and nail colouring. Pulse oximetry is capable of recording accurate measurements through most nail polish colours, but removal is still considered good practice. Contact lenses, false eyelashes, and eye makeup also must be removed. The patient's glasses can be stored or given to the family immediately before the patient enters the OR.

Removal of Prostheses. It is easy for any type of prosthetic device to become lost or damaged during surgery. The patient must remove all prostheses, including partial or complete dentures, artificial limbs, artificial eyes, and hearing aids. If a patient has a brace or a splint, check with the physician to determine whether it should remain with the patient.

Many patients are embarrassed at having to remove dentures, wigs, or other devices that enhance their personal appearance. Privacy should be offered as these personal items are removed. Patients may be allowed to keep personal items until they reach the preoperative area. For safekeeping, dentures must be placed in special containers labelled with the patient's name and other identification required by the agency. In many institutions, nurses must make an inventory of all prosthetic devices or personal items and lock them away according to agency policy. It is also common practice for nurses to give prostheses to family members or to keep items like dentures at the patient's bedside. Documentation in the nursing notes, the surgical checklist, or per agency policy should reflect these actions.

Safeguarding Valuables. If a patient has any valuables, you should give them to family members or secure them for safekeeping. Many hospitals require patients to sign a release form that frees the institution of responsibility for any lost valuables. Valuables usually can be stored and locked in a

designated location. Often patients are reluctant to remove wedding rings or religious medals. A wedding band can be taped in place. However, if there is a risk that the patient will experience swelling of the hand or fingers (related to mastectomy, hand surgery, or fluid shifts), the wedding band should be removed. Many hospitals allow patients to pin religious medals to their gowns, although the risk of loss increases with this practice. For safety, other metal items, such as for pierced areas, should also be removed. The location of valuables is documented per hospital policy.

Preparing the Bowel and Bladder. The patient may require an enema or cathartic on the morning of surgery to ensure that the colon is empty. If so, it should be given at least one hour before the patient is scheduled to leave for surgery, allowing time for the patient to defecate without rushing. You should instruct the patient to void just before leaving for the OR and before giving preoperative medications. An empty bladder prevents a patient from becoming incontinent during surgery. This is important during abdominal surgery, when it may be necessary for the surgeon to manipulate the bladder. An empty bladder also makes abdominal organs more accessible during surgery. The last time of voiding is charted. If the patient is unable to void, this should be noted on the preoperative (preprocedure) checklist. An in-dwelling urinary catheter may be placed if the surgery is long or the incision will be in the lower abdomen.

Vital Signs. You must measure a final preoperative set of vital signs. The anesthesiologist uses these values as a baseline during surgery. If preoperative vital signs are abnormal, surgery may need to be postponed. Notify the physician of any abnormalities before sending the patient to surgery.

Documentation. Before the patient goes to the OR, check the contents of the medical record to ensure that pertinent laboratory results are present. Any abnormal findings in laboratory results, such as low potassium, should be reported. Check consent forms for accuracy of information. A preoperative or preprocedure checklist (Figure 48-5) provides you with guidelines to ensure that nursing interventions are completed. You should also check the nursing notes to ensure that documentation of care is current. This is especially important if the hospitalized patient experienced unpredicted problems on the night before surgery. The OR should be alerted through notation of any positioning challenges for the patient, such as difficulty flexing knees, or of any sensory impairment.

Performing Special Procedures. A patient's condition may warrant special interventions before surgery. The patient may need IV infusions started or a nasogastric tube inserted before leaving for surgery. These procedures also may be done once the patient is in the preoperative area, but are usually done in the OR.

Administering Preoperative Medications. The advent of ambulatory surgery has reduced the use of preoperative medications. However, the anesthesiologist or surgeon may order preanesthetic drugs ("on-call medications," "pre-ops") to reduce the patient's anxiety, the amount of general anesthesia required, the risk of nausea and vomiting and resultant aspiration, and respiratory tract secretions.

You should provide all nursing care measures before giving the patient preoperative medications at the prescribed time. The consent form needs to be signed before the administration of these medications. In addition, the patient should be helped to void. Because the drugs cause sedation, the patient should not be allowed to leave the bed or stretcher until surgical

personnel arrive to transport him or her to the OR. The patient should be warned to expect drowsiness and a dry mouth.

safety alert Explain to the patient the effects of the preoperative medications. Remind the patient to remain in bed or on the stretcher. Raise the side rails and keep the bed or stretcher in the low position. Place the call light within easy reach of the patient.

Latex Sensitivity or Allergy. As the incidence and prevalence of latex sensitivity and allergy increases, the need to recognize potential sources of latex is critical. The Canadian Society of Hospital Pharmacists (2001) released new guidelines recommending procedures to prevent and treat occupational latex allergies. Guidelines developed through Canadian and American health care organizations are also available for the management of latex allergies and safe latex use in health care facilities (Sussman & Gold, 2004).

The OR and PACU can contain innumerable products that have latex in them. Some common sources are gloves, IV tubing, syringes, and rubber stoppers on bottles and vials. Latex is also present in objects that may be overlooked, such as adhesive tape, disposable electrodes, endotracheal tube cuffs, protection sheets, and ventilator equipment. However, many hospitals have moved to latex-free products. Those most at risk are people with a previous sensitivity to latex or rubber products, people with neural tube defects such as spina bifida, patients with a history of multiple surgeries, health care providers, and those with history of contact dermatitis or atopic immunological reactions (OPANA, 2009). Symptoms of a latex reaction can include local effects ranging from urticaria and flat or raised red patches to vesicular, scaling, or bleeding eruptions. Acute dermatitis also may be present. Rhinitis and rhinorrhea are other common symptoms in both mild and severe latex reactions. Immediate hypersensitivity reactions can be life-threatening, with the patient exhibiting focal or generalized urticaria, edema, bronchospasm, and mucous hypersecretion, which can compromise respiratory status. Vasodilatation compounded by increased capillary permeability can lead to circulatory collapse and eventual death. Because the patient may be draped during surgery, any unexplained acute deterioration in a previously healthy patient should be investigated for possible latex allergy (Shoup, 1998).

Protocols exist for patients with a latex allergy or sensitivity. Patients with this allergy are identified preoperatively. Latex-free kits are available; they include latex-free equipment (e.g., a latex-free ambu bag) and follow the patients throughout their hospitalization. Although latex kits are available, the move to latex-free products has decreased their use. A reference binder is kept that indicates supplies, medications, and appropriate care options for latex-sensitive patients. It is recommended that the patient with a latex allergy be scheduled as the first case of the day in the OR (OPANA, 2009). The patient can then be safely accommodated by using appropriate latex-free items during the perioperative period and recovery. Box 48-5 lists precautions for patients with latex sensitivity or allergy.

Surgical Safety Checklist. The World Health Organization (WHO, 2008) has a surgical safety checklist, a tool designed by experts in surgery, anesthesia, and nursing. This tool fosters communication between surgeons and nurses about a patient's condition and risk factors at critical time points: during Sign In, Time Out (Surgical Phase), and Sign Out. This

EVIDENCE-INFORMED
PRACTICE GUIDELINE

Latex Precautions

1. Survey the patient care area and remove any products containing latex (e.g., examination gloves, rubber sheets, or blood pressure cuff).
2. Place a latex precautions label on the patient's chart and latex precautions signs on the door to the patient's room and on the transport cart.
3. Use only nonlatex gloves. Order an adequate supply.
4. Review the supplies to be used for the patient and substitute with latex-free supplies as necessary.
5. Review the medications to be administered and verify that they are latex-free. Include the following steps:
 - a. Notify the pharmacy of the need for latex precautions.
 - b. Verify that all prescribed medications are latex-free.
 - c. Place a sign in the area where medications (including mixing solutions) are kept, indicating that the patient is on latex precautions.
 - d. Use latex-free syringes.
6. Review the intravenous supplies to be used and verify that they are latex-free. Include the following steps:
 - a. Use latex-free solutions.
 - b. Use latex-free tubing.
 - c. Use latex-free syringes, including those for patient-controlled analgesia.
 - d. Use latex-free tape.
7. Verify that bedding and support garments are latex-free (e.g., mattress protectors, anti-embolism stockings, and binders).
8. Verify that dressings and tape are latex-free.
9. Notify the family and visitors of the use of latex precautions.
10. Routinely survey the patient care area to verify that latex products are not present (e.g., examination gloves, balloons).
11. Before transfer to another area or agency, notify care providers of the need for latex precautions.
12. Provide education programs about latex allergy to health care providers, patients, and family or caregivers. This education should include the following:
 - a. Definition of latex allergy
 - b. Exposures to latex
 - c. Latex avoidance
 - d. Signs and symptoms of a reaction to latex
 - e. Emergency treatment of a reaction to latex

checklist is endorsed by the Canadian Patient Safety Institute (CPSI) (Canadian Patient Safety Institute, 2009).

Eliminating Wrong Site and Wrong Procedure Surgery. Whenever an invasive surgical procedure is to be performed, you and the surgeon must ensure that the site has been marked by the surgeon (see agency policy). Indelible ink may be used to mark left and right distinction, multiple structures (e.g., fingers), and levels of the spine. You also must verify the patient and the procedure to be performed. In addition, once the patient reaches the OR, he or she is introduced to the surgical team. The patient is asked to describe what

Figure 48-6 Critical thinking model for surgical patient evaluation.

procedure is being performed and to indicate the site for the surgery. The consent form is verified.

❖ Evaluation

Patient Care

The nurse in the preoperative area will be the source for evaluating outcomes during the preoperative period (Figure 48-6). With regard to the preoperative patient's care plan, limited time is available to evaluate the outcomes. The patient's current status is compared with expected outcomes to determine whether new or revised interventions or nursing diagnoses need to be implemented.

Because interventions continue during and after surgery, evaluation of many goals and outcomes do not occur until after surgery. For example, you will not be able to evaluate the success in preventing postoperative wound infection or promoting return of normal physiological function until a few days after surgery. If the patient is having ambulatory surgery, he or she will return home; therefore, the effectiveness of certain interventions is evaluated at follow-up appointments.

Patient Expectations

Determining whether the patient's expectations have been met regarding preoperative teaching may be difficult. You are evaluating the patient in a hurried atmosphere because there are many things that need to be accomplished in a short amount of time. The patient's surgery may be an emergency, or performance of various procedures may make it difficult for you to

find time for evaluation. It is important that you remember to attend to the patient's emotional needs (privacy, fear, anxiety), as well as to his or her physical needs. The patient should be given an opportunity to state whether expectations have been met. If expectations have not been met, you will need to work closely with the patient to redefine expectations that can be realistically met within the time limits imposed by the particular setting.

Transport to the Operating Room

Personnel in the OR notify the nursing division or ambulatory surgery area when it is time for the patient's surgery. In many hospitals, an orderly or transporter brings a stretcher for transporting the patient. The transporter checks the patient's identification bracelet against the patient's chart to ensure that the right person is going to surgery. Because the patient may have received preoperative drugs, the nurses and transporter assist the patient when transferring from bed to stretcher to prevent falls. The ambulatory surgery patient may ambulate to the OR if able to do so and not medicated. Provide the family with an opportunity to visit before the patient is transported to the OR. Then direct the family to a waiting area. In some hospitals, the family may be allowed to wait with the patient in the OR holding area until he or she is transported into the OR.

After the patient leaves the nursing unit, you should prepare the bed and the room for the patient's return, if the patient is returning to the same nursing unit. A postoperative bedside patient area should include the following:

- Sphygmomanometer, stethoscope, and equipment to take a temperature
- Emesis basin
- Clean gown
- Washcloth, towel, and facial tissues
- IV pole and, often, IV pump
- Suction equipment (if needed)
- Oxygen equipment (if needed)
- Extra pillows for positioning the patient comfortably
- Bed pads to protect bed linens from drainage
- Bed raised to stretcher height with bed linens pulled back and furniture moved to accommodate the stretcher and equipment (such as IV lines)

Intraoperative Surgical Phase

Care of the patient during surgery requires careful preparation and knowledge of the events that occur during the surgical procedure. The nurse usually functions in one of two roles in the OR: circulating nurse or scrub nurse. The **circulating nurse** must be a registered nurse. Responsibilities of this nurse include reviewing the preoperative assessment, establishing and implementing the intraoperative care plan, evaluating the care, and providing for continuity of care postoperatively. The circulating nurse assists with procedures, such as endotracheal intubation as needed. In addition, this nurse monitors sterile technique and a safe OR environment, assists the surgeon and surgical team by providing additional supplies, verifying sponge and instrument counts, and maintaining accurate and complete written records.

The **scrub nurse** may be a registered nurse or a registered practical nurse. This nurse maintains a sterile field during the surgical procedure, assists with applying sterile drapes, hands

the surgeons instruments and other sterile supplies, and completes sponge and instrument counts.

Preoperative (Holding) Area

In most hospitals, the patient enters a holding area outside the OR. As the nurse in the holding area, you validate the patient's identification and the location of the surgery. You verify that appropriate data have been obtained, assess a patient's readiness both physically and emotionally, and reinforce teaching (Sullivan, 2000). Nurses in the holding area are members of the OR staff and wear surgical scrub suits, hats, and footwear in accordance with infection control policies. In some ambulatory surgical settings, a perioperative primary nurse admits the patient, circulates for the operative procedure, and manages the patient's recovery and discharge.

In the preoperative area, you or the anaesthesiologist may insert an IV catheter into the patient's arm to establish a route for fluid replacement and IV drugs. A large-bore (18-gauge) IV catheter is used for easy infusion of fluids and blood products if necessary. You also apply a blood pressure cuff. The cuff will remain in place throughout the surgery so that the anaesthesiologist can assess blood pressure readings. You usually review the preoperative checklist, and the anaesthesiologist may perform a patient assessment at this time.

If any preoperative medications have been given, the patient begins to feel drowsy. The temperature in the holding area and adjacent OR suites is usually cool, and the patient should be offered an extra blanket. The patient's stay in the holding area is usually brief.

Admission to the Operating Room

Nurses transfer the patient to the OR via a stretcher. Usually the patient is still awake and will notice nurses and physicians wearing complete surgical masks, gowns, and eyewear. The staff carefully transfers the patient to the OR table, after ensuring that the stretcher and table are locked in place. After the patient is on the table, fasten a safety strap around the patient. Support the patient by explaining procedures and encouraging the patient to ask questions. Sights and sounds in the surgical suite can seem frightening to patients.

The Nursing Process in the Intraoperative Surgical Phase

◆ Assessment

In the holding area, conduct a focused preoperative assessment to verify that the patient is ready for surgery and to plan intraoperative care. Because patients will not be able to speak for themselves while under general anaesthesia, this preoperative assessment in the OR is important for the patient's safety.

safety alert Verification of the patient's name by patient response compared with chart and ID bracelet is completed before sedation. The chart is reviewed for consent forms, allergies, medical history, physical assessment findings, test results, and verification of preoperative medications. You verify with the patient the planned surgical procedure and the surgical site before anaesthesia is administered. Some agencies ask the patient to mark the surgical site. You ensure that the patient's prosthetic devices and valuables have been removed.

You review the preoperative care plan to establish an intraoperative care plan and assess the patient's psychological comfort.

❖Nursing Diagnosis

You review preoperative nursing diagnoses and modify them to individualize the care plan in the OR.

❖Planning

Goals and Outcomes

Patient-centred outcomes of preoperative care extend into the intraoperative phase. For example, one goal would be to maintain skin integrity. An expected outcome would be that the patient will have intact skin and show no signs of redness.

❖Implementation

A primary focus of intraoperative care is to prevent injury and complications related to anaesthesia, surgery, positioning, and equipment used. The perioperative nurse serves as an advocate for the patient during surgery and protects the patient's dignity and rights at all times.

Physical Preparation. After safely securing the patient on the OR table, apply monitoring devices to the patient before surgery. Patients receiving general and regional anaesthesia undergo continuous ECG monitoring during surgery. Small plastic electrodes are placed on the chest and extremities to record electrical activity of the heart. A monitor in the OR displays the heart's electrical activity. Pulse oximetry will be used to monitor oxygen saturation. An electrical cautery grounding pad is applied to the skin. **Antiembolism stockings** or **sequential compression devices** may be applied intraoperatively (especially during long surgeries) or postoperatively according to agency policy (see Chapter 45). Document device application and patient tolerance to procedures.

Introduction of Anaesthesia. Patients undergoing surgical procedures receive one of four types of anaesthesia: general, regional, local, or conscious sedation.

General Anaesthesia. Modern anaesthetic agents are much easier to reverse and allow the patient to recover with fewer untoward effects. **General anaesthesia** results in an immobile, quiet patient who does not recall the surgical procedure. The patient's amnesia acts as protection from the unpleasant surgical events. An anaesthesiologist gives general anaesthetics by IV and inhalation routes through the three phases of anaesthesia: induction, maintenance, and emergence. Surgery that requires general anaesthesia involves major procedures with extensive tissue manipulation or the desire for analgesia, muscle relaxation, immobility, and control of the autonomic nervous system.

Induction includes the administration of anaesthetic agents and endotracheal intubation. The maintenance phase includes positioning the patient, preparing the skin for incision, and the surgical procedure itself. Appropriate levels of anaesthesia are maintained during this phase. During emergence, anaesthetics are decreased and the patient begins to awaken. Because of the short half-life of current medications, emergence often begins to occur in the OR.

The duration of anaesthesia depends on the length of surgery. The greatest risks from general anaesthesia are the side effects of anaesthetic agents, including cardiovascular

depression or irritability, respiratory depression, and liver and kidney damage.

Regional Anaesthesia. Induction of **regional anaesthesia** results in loss of sensation in an area of the body. The method of induction influences the portion of sensory pathways that are anaesthetized. No loss of consciousness occurs with regional anaesthesia, but the patient may be sedated. The anaesthesiologist gives regional anaesthetics by infiltration and local application. Administration techniques include nerve blocks, intrathecal (spinal) or epidural anaesthesia, and IV regional anaesthesia. With epidural anaesthesia, a spinal needle is progressed into the epidural space, while with intrathecal anaesthesia, it is into the subarachnoid space. Both epidural and intrathecal anaesthesia affect motor, sensory, and sympathetic nerves. With intrathecal, the onset of anaesthesia is faster and the amount of medication required is much less than with epidural anaesthesia.

Infiltrative anaesthetics do involve risks, particularly in the case of intrathecal (spinal) anaesthesia. Because the level of anaesthesia may rise, which means that the anaesthetic agent moves upward in the spinal cord, breathing may be affected. This migration of the anaesthetic agent depends on the drug type, amount, and patient position. If the level of anaesthesia rises, respiratory paralysis may develop, requiring resuscitation. Elevation of the upper body prevents respiratory paralysis. The patient may experience a sudden fall in blood pressure, which results from extensive vasodilation caused by the anaesthetic block to sympathetic vasomotor nerves and pain and motor nerve fibres. The patient requires careful monitoring during and immediately after surgery.

Because the patient is responsive and capable of breathing voluntarily, it is not necessary for the anaesthesiologist to use an endotracheal tube. OR personnel can gain a false sense of security because of the patient's relative alertness. Nurses must remember that burns and other trauma can occur on the anaesthetized part of the body without the patient's being aware of these injuries. Therefore, nurses must observe the position of the extremities and the condition of the skin frequently.

Local Anaesthesia. **Local anaesthesia** involves loss of sensation at the desired site (e.g., a growth on the skin or the cornea of the eye). The anaesthetic agent (e.g., lidocaine) inhibits nerve conduction until the drug diffuses into the body's circulation. It may be injected locally or applied topically. The patient experiences a loss in pain and touch sensation at the site. Local anaesthesia is commonly used for minor procedures performed in ambulatory surgery. Physicians may infiltrate the operative area with local anaesthetics to promote postoperative pain relief. For example, peripheral nerve blocks produce anaesthetic effect both at and distal to the site of injection (Turjanica, 2007).

Conscious Sedation. **Conscious sedation** is routinely used for procedures that do not require complete anaesthesia but rather a depressed level of consciousness. A patient under conscious sedation must independently retain a patent airway and airway reflexes and must be able to respond appropriately to physical and verbal stimuli (Litwack, 1999). Short-acting IV sedatives, such as midazolam, are given.

Advantages of conscious sedation include adequate sedation and reduction of fear and anxiety with minimal risk, amnesia, relief of pain and noxious stimuli, mood alteration, elevation of pain threshold, enhanced patient cooperation, stable vital signs, and rapid recovery. A variety of diagnostic

and therapeutic procedures are appropriate for conscious sedation (burn dressing changes, some cosmetic surgery, pulmonary biopsy and bronchoscopy, colonoscopy, and many others) (Litwack, 1999). Nurses assisting with the administration of local anaesthesia and conscious sedation must demonstrate competency in the care of these patients. Knowledge of anatomy, physiology, cardiac dysrhythmias, procedural complications, and pharmacological principles related to the administration of individual agents is essential. Nurses also must be able to assess, diagnose, and intervene in the event of untoward reactions and demonstrate skill in airway management and oxygen delivery. Resuscitation equipment must be readily available when local anaesthesia or conscious sedation is used (AORN, 2002a).

Positioning the Patient for Surgery. When general anaesthesia is being used, the nursing personnel and surgeon often do not position the patient until the stage of complete relaxation is achieved. The choice of position is usually determined by the surgical approach. Ideally, the patient's position provides good access to the operative site and sustains adequate circulatory and respiratory function. It should not impair neuromuscular structures. The patient's comfort and safety must be considered.

Normal range of joint motion is maintained in an alert person by pain and pressure receptors. If a joint is extended too far, pain stimuli provide a warning that muscle and joint strain is too great. In a patient who is anaesthetized, normal defence mechanisms cannot guard against joint damage, muscle stretch, and strain. The muscles are so relaxed that it is relatively easy to place the patient in a position the individual normally could not assume while awake. The patient then remains in a given position, often for several hours. Although it may be necessary to place a patient in an unusual position, attempt to maintain correct alignment and protect the patient from pressure, abrasion, and other injuries. Attachments to the operating table allow protection and padding of extremities and bony prominences. Positioning should not impede normal movement of the diaphragm or interfere with circulation to body parts. If restraints are necessary, pad the area to be restrained to prevent skin trauma.

Documentation of Intraoperative Care. During the intraoperative phase, the nursing staff continues the preoperative care plan. For example, strict asepsis must be followed to minimize the risk of surgical wound infection. IV fluid infusion and monitoring of urinary and nasogastric output are examples of actions nurses will take to maintain the patient's fluid balance. Throughout the surgical procedure, keep an accurate record of patient care activities and procedures performed by OR personnel. Documentation of intraoperative care provides useful data for the nurse who will care for the patient postoperatively.

❖Evaluation

Interventions implemented during the intraoperative phase are evaluated throughout the surgical procedure.

Patient Care

Nurses perform intraoperative evaluation of the patient. Vital signs and intake and output are monitored continuously. The patient's body temperature is measured during the procedure and on completion of the surgical procedure. The skin is inspected under the grounding pad and at areas where

pressure from positioning may have been exerted. Schoonhoven et al. (2002) conducted research related to the development of pressure ulcers during surgery that lasts more than four hours. Of the 208 patients in their study, 44 developed ulcers in the first two days after surgery. Therefore, careful monitoring and preventive measures must be taken during and after surgery.

Patient Expectations

Nurses should frequently question patients not undergoing general anaesthesia regarding pain, numbness, perceived room temperature, and overall comfort. The circulating nurse provides updates to family members in the waiting room.

Postoperative Surgical Phase

After surgery, a patient's care can become complex as a result of physiological changes that may occur. Patients who have undergone general anaesthesia are more likely to face complications than those who have had only local anaesthesia or conscious sedation. The patient who has had general anaesthesia usually has undergone extensive surgery as well. In contrast, an ambulatory surgical patient who has had local anaesthesia with no sedation and has stable vital signs may be discharged immediately. A patient who has undergone regional or general anaesthesia usually is transferred to the PACU to be stabilized before discharge to the nursing unit or back to the ambulatory surgery area.

To assess a patient's postoperative condition, you must apply critical thinking while relying on information from the preoperative nursing assessment, knowledge regarding the surgical procedure performed, and events occurring during surgery. This information helps you detect any changes and make decisions about the patient's care. A variation from the patient's norm may indicate the onset of surgery-related complications. Along with the anaesthesiologist, the circulating nurse may accompany the patient to the PACU and report to the nurse to provide continuity of care.

A patient's postoperative course involves two phases: the immediate recovery period and postoperative convalescence. For an ambulatory surgical patient, recovery normally lasts only one to two hours, and **convalescence** occurs at home. For a hospitalized patient, recovery may last a few hours, and convalescence occurs in hospital over one or more days, depending on the extent of the surgery and the patient's response to it.

Immediate Postoperative Recovery

Before the patient arrives in the PACU, the PACU nurse obtains data from the surgical team in the OR regarding the patient's general status and the need for special equipment and nursing care. Careful planning allows the nursing staff to consider placement of patients in the PACU. For example, patients who have undergone spinal anaesthesia are aware of their surroundings and may benefit from being in a quieter part of the PACU, away from patients who need frequent monitoring. The patient with a serious infection such as tuberculosis should be isolated from other patients. Standard precautions or routine practices for infection control are used for all patients (see Chapter 32). Nurses must be familiar with agency and professional protocols related to preventing respiratory infection transmission (Ontario Ministry of Health and Long-Term Care, 2004).

Figure 48-7 Postanaesthesia care unit.

When the patient is admitted to the PACU, the PACU personnel notify the patient care area of the patient's arrival. This allows the nursing staff to inform family members. Usually, nurses would advise family members to remain in the designated waiting area so that they can be found when the surgeon arrives to explain the patient's condition. The surgeon is responsible for describing the patient's status, the results of surgery, and any complications that may have been encountered. Nurses can be a valuable resource to the family if complications arose during the operative phase.

When the patient enters the PACU (Figure 48-7), nurses and members of the surgical team confer about the patient's status. The surgical team's report includes a review of anaesthetic agents administered so that nurses can anticipate both how quickly a patient should regain consciousness and his or her analgesic needs. A report on IV fluids or blood products administered during surgery alerts nurses to the patient's fluid and electrolyte balances. The surgeon often reports any special concerns (e.g., whether the patient is at risk for hemorrhaging or infection). The anaesthesiologist discusses whether there were complications during surgery, such as excessive blood loss or cardiac irregularities. Frequently, this report takes place while PACU nurses are admitting the patient. You will attach the patient to monitoring equipment such as the noninvasive blood pressure monitor, ECG monitor, and pulse oximeter. Patients usually receive some form of oxygen in this immediate recovery period. Take vital signs when the patient arrives and confirm these with the surgical team.

After reviewing events in the OR, make a complete assessment of the patient's status. This assessment should be performed rapidly and thoroughly and be targeted to the needs of the postsurgical patient. Standards of perianaesthetic nursing practice, such as those of OPANA (2009), function as a guide for agencies in outlining the urgent nature and components of the admission assessment as well as ongoing monitoring of patient status. A systems approach to assessment is discussed in a later section outlining the nursing process in postoperative care. Nursing care in the PACU focuses on monitoring and maintaining respiratory, circulatory, neurological, and fluid and electrolyte status; assessing wound status; and assessing and managing pain (see "The Nursing Process in Postoperative Care").

TABLE 48-8 Modified Aldrete Score

Parameter	Task	Score
Activity	Able to move four extremities voluntarily or on command	2
	Able to move two extremities voluntarily or on command	1
	Unable to move extremities voluntarily or on command	0
Respiration	Able to breathe deeply and cough freely	2
	Dyspnea or limited breathing	1
	Apneic	0
Blood pressure	$\pm 20\%$ of preanaesthetic level	2
	$\pm 20\%$ – 49% of preanaesthetic level	1
	$\pm 50\%$ of preanaesthetic level	0
Consciousness	Fully awake	2
	Arousable on calling	1
	Not responding	0
Oxygen saturation	SpO ₂ $>94\%$ on room air	2
	Needs O ₂ inhalation to maintain SpO ₂ $>94\%$	1
	SpO ₂ $<94\%$ even with extra O ₂	0
Total

Discharge From the Postanaesthesia Care Unit

Nurses evaluate readiness for discharge from the PACU by comparing vital sign stability with the preoperative data. Other outcomes for discharge are body temperature control, good ventilatory function, orientation to surroundings, absence of complications, minimal pain and nausea, controlled wound drainage, adequate urine output, and fluid and electrolyte balances. Patients who had more extensive surgery that required anaesthesia of longer duration usually recover more slowly. Many PACU staff use an objective scoring system that helps to delineate when patients may be discharged. The Aldrete score, or the **Postanesthesia Recovery Score (PARS)**, is the most widely used scoring tool (Table 48-8). The patient must receive a composite score of 8 to 10 before discharge from the PACU. Some agencies have modified this scoring system; for example, some remove movement of extremities and add presence of pain, and some agencies require that the patient have a composite score of 10 before discharge from the PACU. If the patient's condition is still poor after two to three hours, the stay in the PACU lengthens or the surgeon may transfer the patient to an intensive care unit.

When the patient is ready to be discharged from the PACU, you may call the nursing unit to report the patient's status, including vital signs, respiratory status, the type of surgery and anaesthesia performed, any complications that occurred during surgery or in the PACU, blood loss, level of consciousness, general physical condition, type and amount of fluids received, and presence of IV lines, drainage tubes, and dressings. You also should review physician orders that require attention. Your report helps the nurse in the acute patient care area to anticipate special patient needs and obtain

necessary equipment. Any outstanding family issues are also addressed.

Orderlies or other personnel, who might include nurses, transport the patient on a stretcher. Usually the PACU nurse does not accompany the patient to the surgical unit, but a verbal report will be given to the acute care nurse reviewing the patient's condition and course of care. Some institutions have policies related to which patients must be accompanied by a nurse, such as those who have experienced recent seizure activity or who have had upper airway surgery. Staff members assist in safely transferring the patient to a bed (see Chapter 35).

Recovery in Ambulatory Surgery

The thoroughness and extent of postoperative recovery care depends on the ambulatory patient's condition, type of surgery, and anaesthesia. There are two phases of postanesthesia recovery. During phase I, you focus on helping the patient safely transition from a totally anaesthetized state to one requiring less acute interventions. After patients become stable and no longer require such intensive monitoring, you transfer them to phase II recovery. During phase II, you focus on continuing the recovery process, addressing the patient's needs, and preparing the patient and family for discharge from phase II (OPANA, 2009).

With new anaesthetic agents and techniques, patients experience a more rapid awakening in the OR (Apfelbaum et al., 2002; Fredman et al., 2002; Saar, 2001). Therefore, some ambulatory surgery patients may bypass phase I. This is known as fast tracking (White et al., 2003). Phase II recovery may consist of a room equipped with medical recliner chairs, side tables, and footrests. Kitchen facilities for preparing light snacks and beverages are usually located in the area, along with bathrooms. Aldrete (1998) has added five more areas of functional assessment for the ambulatory surgery patient, which constitute the **Postanesthesia Recovery Score for Ambulatory Patients (PARSAP)** (Table 48-9). The phase II environment is designed to promote both the patient's and the family's comfort and well-being until discharge. You continue to monitor patients but not at the same intensity as during phase I. In phase II recovery, you initiate postoperative teaching with patients and family members (Box 48-6).

Ambulatory surgical patients are discharged to home when they meet certain criteria. A patient being monitored by PARSAP must achieve a score of 18 or higher before being discharged. An exception may be allowed if the patient was unable to walk or move his or her extremities before surgery (Aldrete, 1998). Postoperative nausea and vomiting may occur once the patient is home even if the symptoms were not present at the time of discharge. Options for therapy include the prophylactic use of the drug ondansetron (an orally disintegrating tablet), transcutaneous acupoint electrical stimulation, or a transdermal scopolamine patch (Gan, 2002).

Written postoperative instructions and prescriptions are reviewed with the patient and the family, and you should ensure that they verbalize understanding of these instructions. The patient is discharged to the care of a responsible adult.

Postoperative Convalescence

Inpatient patients are kept in the PACU until their conditions stabilize; they are then transported to the postoperative nursing unit. Ambulatory surgery patients will return home. Nursing care focuses on returning the patient to a relatively functional

► TABLE 48-9

Expanded Postanaesthetic Recovery Score for Ambulatory Patients

Parameter	Task	Score
Activity	Able to move four extremities voluntarily or on command	2
	Able to move two extremities voluntarily or on command	1
	Unable to move extremities voluntarily or on command	0
Respiration	Able to breathe deeply and cough freely	2
	Dyspnea or limited breathing	1
	Apneic	0
Blood pressure	±20% of preanaesthetic level	2
	±20%–49% of preanaesthetic level	1
	±50% of preanaesthetic level	0
Consciousness	Fully awake	2
	Arousable on calling	1
	Not responding	0
Oxygen saturation	SpO ₂ >94% on room air	2
	Needs O ₂ inhalation to maintain SpO ₂ >94%	1
	SpO ₂ <94% even with extra O ₂	0
Dressing	Dry and clean	2
	Wet but marked and not increasing	1
	Growing area of wetness	0
Pain	Pain-free	2
	Mild pain handled by oral medication	1
	Severe pain requiring parenteral medication	0
Ambulation	Able to stand up and walk straight*	2
	Vertigo when erect	1
	Dizziness when supine	0
Fasting or feeding	Able to drink fluids	2
	Nauseated	1
	Nausea and vomiting	0
Urine output	Has voided	2
	Unable to void but comfortable	1
	Unable to void and uncomfortable	0

Total

Note: Total score must be at least 18 for patient to be discharged to home.
 *May be substituted by Romberg's test, or by picking up 12 clips in one hand.
 Adapted from Aldrete, J. A., & Kroulik, D. (1970). A post-anesthetic recovery score. *Anesthesia and Analgesia*, 49, 924–934; and Aldrete, J. A. (1998). Modifications to the post-anesthesia score for use in ambulatory surgery. *Journal of Perianesthesia Nursing*, 13, 148.

level of wellness as soon as possible. The speed of convalescence depends on the type or extent of surgery, the risk factors involved, and any postoperative complications.

The Nursing Process in Postoperative Care

Nursing care in the PACU focuses on managing pain and monitoring and maintaining respiratory, circulatory, fluid and electrolyte, and neurological status. Other important factors

* BOX 48-6 PATIENT TEACHING

Postoperative Instructions for Ambulatory Surgical Patients

Objectives

- Patient will verbalize resources to contact for assistance.
- Patient will describe signs and symptoms of postoperative problems.
- Patient will list the name and dose of medications to self-administer.
- Patient will describe guidelines related to specific surgery.

Teaching Strategies

- Provide instruction sheet with physician's or nurse's telephone number, surgery centre's number, and follow-up appointment date and time. Allow patient and family to ask questions.
- Explain to family members the signs and symptoms of infection for which to observe.
- Explain name, dose, schedule, and purpose of medications. Provide drug information leaflets.
- Explain activity restrictions, diet progression, and any special wound care related to specific surgery. Provide instruction sheet with clear, focused explanations.

Evaluation

- Ask patient to describe signs indicating potential problems and normal convalescence.
- Ask patient to explain when and how to call health care providers such as the home care nurse.
- Ask patient to recite date for follow-up appointment.
- Ask patient and family members to describe the signs and symptoms of infection.
- Ask patient to verbalize name of drug, dose, and when to take.
- Ask patient to demonstrate proper activity or movement and wound care.

to assess include temperature control, skin and incision or wound status, and genitourinary and gastrointestinal function. However, these factors are not unique to the PACU setting. The nurse in the acute care unit continues to assess these critical factors until the patient's discharge from the acute care facility.

❖ Assessment

After patient assessment upon arrival to the PACU, the nurse repeats evaluation of vital signs and other key observations at least every 15 minutes or more frequently, depending on the patient's condition and unit policy. This assessment usually continues until discharge from the PACU. Once the patient is returned to the surgical unit, the nurse admitting the patient takes vital signs immediately in order to compare them with the PACU findings. Vital sign monitoring in the postoperative nursing unit initially should be at least hourly for four hours and then every four hours, unless complications develop. For some institutions, policy may require that vital signs for the patient on return to the surgical unit should be every 15 minutes for the first hour, then hourly for four hours, and then every four hours. Frequency of assessment should always be based on the patient's current condition, which can change rapidly, especially during the postoperative period.

You thoroughly document your assessment, including vital signs, respiratory status, level of consciousness, condition of

dressings and drains, pain and comfort level, skin warmth and colour, ability to move extremities, IV fluid status, and urinary output measurements. Patient data can be entered on flow sheets, by electronic documentation or written progress notes. The initial findings are a baseline for comparing any postoperative changes.

Once the patient returns to the acute care area, you focus on completing the assessment, meeting the patient's immediate needs, and providing an opportunity for the family to be with the patient. The call light and emesis basin should be within the patient's reach. You can explain the purpose of postoperative procedures or equipment and the patient's status. The family should know that the patient will fall in and out of sleep for most of the rest of the day due to the effects of general anaesthesia and pain medication. The family also should be reminded that frequent assessments are to be expected and that limited sensation and movement in the patient's extremities may remain for a few hours if he or she had intrathecal (spinal) or epidural anaesthesia.

Respiration

Certain anaesthetic agents may cause respiratory depression. Thus, you must be especially alert for shallow, slow breathing and a weak cough. You assess airway patency, respiratory rate, rhythm, depth of ventilation, symmetry of chest wall movement, breath sounds, and colour of mucous membranes. If breathing is unusually shallow, placing a hand near the patient's nose or mouth allows you to feel exhaled air. Pulse oximetry should reflect 92% to 100% saturation. Some agencies now have directives that allow nurses to administer oxygen at 3 L/minute via nasal prongs if the patient has a saturation of less than 92%.

The patient often has an oral or nasal airway (see Chapter 38) inserted in the OR after removal of the endotracheal tube to maintain a patent airway until the patient can protect his or her airway. As the patient awakens in the PACU, he or she will spit out the airway or you will ask him or her to spit it out. The patient's ability to do so signifies the return of a normal gag reflex.

One of your greatest concerns is airway obstruction. A number of factors can contribute to obstruction, including weak pharyngeal or laryngeal muscle tone from anaesthetics; secretions in the pharynx, bronchial tree, or trachea; and laryngeal or subglottic edema (Litwack, 1999). In the postanaesthetic patient, the tongue causes the majority of airway obstructions. Ongoing assessment of airway patency is crucial. Patients are often kept in side-lying positions until airways are clear.

In the acute care area, you continue to assess respiratory status and breath sounds. Older patients, smokers, and patients with a history of respiratory disease are prone to developing complications such as atelectasis or pneumonia. The patient is also assessed for any signs of shortness of breath with activity.

Circulation

The patient is at risk for cardiovascular complications resulting from actual or potential blood loss from the surgical site, side effects of anaesthesia, electrolyte imbalances, and depression of normal circulatory regulating mechanisms. Careful assessment of heart rate and rhythm, along with blood pressure, reveals the patient's cardiovascular status. A rhythm strip is usually obtained postoperatively, compared with any

preoperative ECG tracings, and mounted on the PACU record. The vital signs are monitored at least every 15 minutes throughout the PACU recovery phase. Preoperative vital signs are compared with postoperative values. The physician should be notified if the patient's blood pressure drops progressively with each check or if the heart rate changes or becomes irregular.

You assess circulatory perfusion by noting capillary refill, pulses, and the colour and temperature of the nail beds and skin. If the patient has had vascular surgery or has casts or constricting devices that may impair circulation, you should assess peripheral pulses and capillary refill distal to the site of surgery. For example, after surgery to the femoral artery, you assess posterior tibial and dorsalis pedis pulses. You also compare pulses in the affected extremity with those in the nonaffected extremity.

A common early circulatory problem is hemorrhage. Blood loss may occur externally through a drain or incision, or internally. Either type of hemorrhage may result in a fall in blood pressure; elevated heart and respiratory rates; thready pulse; cool, clammy, pale skin; and restlessness. Often, the first sign of hemorrhage is restlessness. Signs such as thready pulse and clammy skin are noted much later, after significant blood loss has occurred. The surgeon must be notified if these types of changes are noted. You maintain IV fluid infusion and may need to increase IV replacement fluids. Monitor the patient's vital signs every 15 minutes or more frequently until his or her condition stabilizes. Oxygen may need to be continued. Volume replacement and medications to promote perfusion to vital organs such as the brain may be considered. Plasma expanders (colloids) may be used instead of blood transfusions. Colloids may be made from blood products (i.e., albumin), but artificial colloids, such as hetastarch, are also used (Diepenbrock, 2008). Blood counts and coagulation studies are drawn and sent to the laboratory. The potential for cardiovascular complications remains when the patient is transferred to the acute care area. In that area, you continue to assess the same factors that were identified in the PACU.

Temperature Control

The OR and recovery room environments are kept extremely cool. The patient's anaesthetically depressed level of body function results in a lowering of metabolism and a fall in body temperature. When patients begin to awaken, they complain of feeling cold and uncomfortable. The length of time spent in the OR and laminar flow rooms contributes to heat loss. Surgeries that require an open body cavity also contribute to heat loss. Older adults and pediatric patients are at higher risk for developing problems associated with hypothermia.

In rare instances, **malignant hyperthermia**, a genetically determined condition and a life-threatening complication of anaesthesia, develops. Malignant hyperthermia causes tachypnea, tachycardia, premature ventricular contractions, unstable blood pressure, cyanosis, skin mottling, and muscular rigidity. An elevated temperature occurs late. Although it is often seen during the induction phase of anaesthesia, symptoms may recur 24 to 72 hours postoperatively (Karlet, 1998). Without prompt detection and treatment, it can be fatal.

Temperature is monitored closely in the acute care area. Because an elevated temperature may be the first indication of an infection, you evaluate the patient for a potential source of infection, including the IV site (if present), the surgical incision or wound, and the respiratory and urinary tracts.

The physician must be notified, because further evaluation, including blood, sputum, and urinary cultures, likely will be needed. In elderly patients, fever may not be seen with infection (Litwack, 2006).

Fluid and Electrolyte Balances

Because of the surgical patient's risk for fluid and electrolyte abnormalities, you assess the hydration status and monitor cardiac and neurological function for signs of electrolyte alterations (see Chapter 39). Laboratory values will be monitored and compared with the patient's baseline values.

One of your important responsibilities is monitoring the rate and maintaining the patency of IV infusions. The patient's only source of fluid intake immediately after surgery is through IV catheters. You must inspect the catheter insertion site to ensure that the catheter is properly positioned within a vein so that fluid flows freely. Accurate recording of intake and output helps assess renal and circulatory function. You record the intravenous infusions received as well as any sources of oral intake once peristalsis returns. You measure all sources of output, including urine, surgically placed drains, gastric drainage, and drainage from wounds, and note any insensible loss from diaphoresis. Daily weights may be assessed postoperatively if the patient has a known cardiac or renal history (e.g., heart failure). It is important to compare preoperative and postoperative weights and to be consistent in the scale used, the amount of clothing worn by the patient, and the time of day to obtain accurate weight measurement. Accurate recording of intake and output is crucial. It is also important to be aware of the amount of fluids received in the intraoperative and immediate postoperative period. For example, if large amounts of fluid were received during surgery, the patient may exhibit signs of fluid retention such as pedal edema or abnormal breath sounds.

Neurological Functions

The patient is often drowsy in the PACU. As anaesthetic agents are metabolized, the patient's reflexes return, muscle strength is regained, and a normal level of orientation returns. A patient should at least be oriented to self and to the hospital before discharge from the PACU. Assess gag reflexes (see Chapter 31), hand grips, and movement of the patient's extremities. If the patient has had surgery involving a portion of the neurological system, conduct a more thorough neurological assessment, including assessing pupil size and reaction.

Patients who had regional anaesthesia begin to experience a return in motor function before tactile sensation. You check the patient's sensation along **dermatomes** (segmental skin areas innervated by specific segments of the spinal cord). Knowing where anaesthesia was introduced, you are able to check the distribution of the spinal nerves affected (see Chapter 31). Typically, you assess the dermatome level by touching the patient bilaterally and documenting where he or she feels touch. The sense of touch can be tested using a paper clip, for example. Assessment of extremity strength, movement, and sensation continues to be important if spinal or epidural anaesthesia has been given, although the patient should remain in the PACU until sensation and voluntary movement of the lower extremities have been re-established.

Skin Integrity and Condition of the Wound

In the PACU, nurses assess the condition of the patient's skin, noting rashes, petechiae, abrasions, or burns. A rash may

indicate a drug sensitivity or allergy. Abrasions or petechiae may result from a clotting disorder or from inappropriate positioning or restraining that injures skin layers. Burns may indicate that an electrical cautery grounding pad was incorrectly placed on the patient's skin. Burns or serious injury to the skin should be documented in an incident report (see Chapter 15). You should also make a note if the patient complains of any burning or pain in the eye that could indicate a corneal abrasion.

After surgery, most wounds are covered with a dressing that protects the site and collects drainage. You observe the amount, colour, odour, and consistency of drainage on dressings. Serosanguineous drainage is the most common type of drainage occurring immediately after surgery. You estimate the amount of drainage by noting the number of saturated gauze sponges. If drainage appears on the outer surface of a dressing, another way to assess drainage is by drawing a circle around the outer perimeter of the drainage on the dressing and dating it with the time noted. This way, you can easily note if drainage is increasing (see Chapter 46).

The nurse on the surgical nursing unit usually will have the first opportunity to view and thoroughly assess and document the status of the incision or wound. Initially, it is important to note if wound edges are approximated and no active bleeding or drainage is present. The wound needs to be assessed for redness, swelling, signs of infection, and slipped sutures or staples. Wound assessment is especially important because it forms the baseline for continued monitoring during the patient's hospital stay.

It is also important to assess the patient's mobility level. If the patient is unable or unwilling to turn, pressure ulcer development is a concern. You should use the Braden Scale to determine the patient's risk of developing pressure ulcers (RNAO, 2005). Preventive measures such as a turning schedule and pressure-reduction devices can be instituted (see Chapter 46).

Genitourinary Function

Depending on the surgery, a patient may not regain voluntary control over urinary function for six to eight hours after anaesthesia. An epidural or spinal anaesthetic may prevent the patient from feeling bladder fullness. You should palpate the lower abdomen just above the symphysis pubis for bladder distension or you may use a bladder scanner to identify the amount of urine in the bladder. If the patient has a urinary catheter, there should be a continuous flow of urine of 30 to 50 mL/hour in adults (Metheny, 2000). You observe the colour and the odour of the urine. Surgery involving portions of the urinary tract normally causes bloody urine for at least 12 to 24 hours, depending on the type of surgery. You will provide ongoing assessment of genitourinary function.

Gastrointestinal Function

Anaesthetics slow gastrointestinal motility and may cause nausea. Normally during the immediate recovery phase, faint or absent bowel sounds are auscultated in all four quadrants. You inspect the abdomen for distension that may be caused by an accumulation of gas. In a patient who has had abdominal surgery, distension will develop if internal bleeding occurs; however, this is a late sign of bleeding. Distension also may occur in the patient who develops a **paralytic ileus** as a result of handling of the bowel in surgery.

You closely monitor the patient's initial oral intake for potential aspiration or the presence of nausea and vomiting.

Assessment also includes checking every four to eight hours for return of peristalsis. Routinely, you auscultate the abdomen to detect return of normal bowel sounds; 5 to 30 loud gurgles per minute over each quadrant indicates that peristalsis has returned. High-pitched tinkling sounds accompanied by abdominal distension suggest that the bowel is not functioning properly. You should ask if the patient is passing gas (flatus). This is an important sign indicating normal bowel function. If a nasogastric tube is in place, assess the patency of the tube (see Chapter 44), the colour and amount of any drainage, and (if ordered) the level of suction required.

Pain and Comfort

Pain management is included in the overall aim of ensuring patient comfort. Comfort is also achieved through nursing measures such as bathing and providing clean bedding. As patients awaken from general anaesthesia, the sensation of pain becomes prominent. Pain can be perceived before full consciousness is regained. Acute incisional pain causes patients to become restless and may be responsible for temporary changes in vital signs. It is difficult for patients to begin coughing and undertaking deep breathing exercises when they experience pain. The patient who had regional or local anaesthesia may not experience pain initially because the incisional area is still anaesthetized.

Assessment of the patient's discomfort and evaluation of pain-relief therapies are essential nursing functions. Pain scales are an effective method for nurses to assess postoperative pain, evaluate response to analgesics, and objectively document pain severity (see Chapter 41). By frequently assessing pain, you can evaluate the effectiveness of interventions (e.g., positioning, analgesics) throughout the patient's recovery.

Patient Expectations

The nurse assesses the patient's and family's expectations and perceived progress in the recovery and convalescence phases. Ongoing assessment of expectations regarding pain control, comfort level, dietary intake, activity level, and readiness for discharge are also performed. You determine the patient's and the family's expectations regarding needs at home and incorporate these into the care plan.

❖Nursing Diagnosis

You determine the status of problems identified from preoperative nursing diagnoses, and cluster new relevant data to identify new diagnoses. Previously defined diagnoses, such as *impaired skin integrity*, may continue as a postoperative problem. You may identify new risk factors leading to identification of nursing diagnoses. For example, an older patient who has undergone major abdominal surgery and who has a preexisting problem of reduced hip mobility resulting from arthritis will likely have the diagnosis of *impaired physical mobility*. The surgery itself may add risk factors for the patient. You also consider the needs of a patient's family when making diagnoses. For example, the inability of the family to cope with the patient's condition requires your intervention. Early dialogue with the family can identify any challenges.

❖Planning

Because of the critical nature of the immediate postoperative period, the care plan in the PACU involves close monitoring

of the patient and frequent assessments to ensure a return to stable physiological function. During the convalescent phase, you use current physical assessment data and analysis of the preoperative nursing health history for planning the patient's care. The surgeon's postoperative plan and the institution's clinical pathways are also guidelines. Typical postoperative plans include the following:

- Frequency of vital sign monitoring and other assessments such as oxygen saturation
- Types of IV fluids and rates of infusion
- Postoperative medications (especially those for pain and nausea)
- Resumption of preoperative medications as condition allows (some oral medications will be converted to the IV route with appropriate dose adjustment)
- Fluids and food allowed by mouth
- Level of activity that the patient is allowed to resume
- Position that the patient is to maintain while in bed
- Intake and output
- Laboratory tests and X-ray studies
- Special directions (e.g., surgical drains to suction, tube irrigations, dressing changes)
- Patient teaching and discharge planning

Goals and Outcomes. You consider the effects of the stress of surgery and the limitations it produces when establishing goals, patient outcomes, and nursing interventions for the patient. Measurable outcomes with indicators help to ensure timely and appropriate recovery from surgery. For example, the patient at risk for impaired physical mobility should have specific outcomes that include targeted ambulation (e.g., steps to take and distance down hallway) and range of joint movement. After each outcome is met, the patient ultimately will achieve the goal of independent mobility at a preoperative level or better. You carefully consider all goals of care established during the preoperative surgical phase. The following is an example of goals and outcomes for the postoperative period:

- Patient achieves a return of normal physiological function after surgery.
- Patient's vital signs return to preoperative baseline.
- Patient's airway is patent and respirations are even and unlaboured.
- Patient's temperature returns to baseline. Patient's fluid and electrolyte levels remain balanced.
- Patient verbalizes feeling of increased strength and ability to move.

Setting Priorities

In the PACU, priorities of care include the assessment and stability of the patient's airway; intervention for an impaired airway; assessment of the patient's respiratory, circulatory, neurological, and fluid and electrolyte status; and pain control. As the patient progresses on the acute care unit, priorities should focus on advancement of patient activity to return the patient to preoperative functioning or better. The patient generally will have multiple nursing diagnoses. You may re-establish priorities several times as the patient's health status changes.

Continuity of Care

In the recovery phase, you collaborate on the care plan with staff from respiratory therapy, physiotherapy, occupational therapy, dietary, social work, home care, and other areas to

meet the patient's needs. The goal of all these disciplines is to assist the patient to return to the best possible level of functioning with a smooth transition to home. The family's role in the care plan to foster recovery is also essential.

Implementation

Health Promotion

Primary causes of postoperative complications include the surgical wound, the effects of prolonged immobilization during surgery and convalescence, preoperative risks such as age (Box 48-7), and the influence of anaesthesia and analgesics. Nursing interventions in the postoperative period are directed at preventing complications so that the patient returns to the highest level of functioning possible. Failure of the patient to become actively involved in recovery adds to the risk for complications (Table 48-10). Virtually any body system can be affected. You must consider the interrelationship of all systems and therapies provided.

Maintaining Respiratory Function. To prevent respiratory complications, begin pulmonary interventions early.

* BOX 48-7 FOCUS ON OLDER ADULTS

- Age alone is no longer a parameter for determining the benefit one can achieve from a surgical procedure. Consequently, nurses are caring for many more surgical patients of advanced age and are required to know the age-related factors that affect a surgical procedure (Eliopoulos, 2001).
- Hypothermia and postoperative embolism may be seen in older adults (Clayton, 2008).
- A smaller margin of physiological reserve makes the older adult less able to compensate during the perioperative period for changes that can occur due to infection, hemorrhage, alterations in blood pressure, and fluid and electrolyte abnormalities.
- Older patients are at greater risk for postoperative delirium after procedures such as hip replacement and cardiac surgery (OPANA, 2009). A rapid decline in cognitive function, fluctuations in awareness and orientation, disturbed sleep-wake cycle, and personality and mood changes characterize the typical presentation (Lueckenotte, 2000). Delirium may be the first indicator of infection, fluid or electrolyte imbalances, or deteriorating respiratory or hemodynamic status. The onset of delirium can result in loss of independence, increased morbidity and mortality, and increased health care costs (Inouye, 2006).
- Altered and unexpected drug responses are often related to different pharmacokinetics in the older adult. Thus, when caring for the perioperative older patient, you must be alert to the possibility of a high risk for adverse medication events with the administration of anaesthetic agents and postoperative analgesics, especially narcotics (Lueckenotte, 2000). "Start lower and go slow" should be the guiding principle when medicating older adults because of their slower drug-clearance capability.

► TABLE 48-10 Postoperative Complications

Complication	Cause
Respiratory System	
<i>Atelectasis:</i> Collapse of alveoli with retained mucous secretions. Signs and symptoms include elevated respiratory rate, dyspnea, fever, crackles auscultated over involved lobes of lungs, and productive cough.	Inadequate lung expansion. Anaesthesia, analgesia, and immobilized position prevent full lung expansion. There is greater risk in patients with upper abdominal surgery who have pain during inspiration and repress deep breathing. Poor lung expansion with retained secretions or aspirated secretions.
<i>Pneumonia:</i> Inflammation of alveoli. It may involve one or several lobes of lung. Development in lower dependent lobes of lung is common in immobilized surgical patient. Signs and symptoms include fever, chills, productive cough, chest pain, purulent mucus, and dyspnea.	
<i>Hypoxemia:</i> Inadequate concentration of oxygen in arterial blood. Signs and symptoms include restlessness, dyspnea, high or low blood pressure, tachycardia or bradycardia, diaphoresis, and cyanosis.	Respirations are depressed by anaesthetics or analgesics. Increased retention of mucus with impaired ventilation occurs because of pain or poor positioning.
<i>Pulmonary embolism:</i> Embolus blocking pulmonary arterial blood flow to one or more lobes of lung. Signs and symptoms include dyspnea, sudden chest pain, cyanosis, tachycardia, and drop in blood pressure.	Same factors lead to formation of thrombus or embolus. Immobilized surgical patient with preexisting circulatory or coagulation disorders is at risk.
Circulatory System	
<i>Hemorrhage:</i> Loss of large amount of blood externally or internally in short period of time. Signs and symptoms include hypotension, weak and rapid pulse, cool and clammy skin, rapid breathing, restlessness, and reduced urine output.	Slipping of suture or dislodged clot at incisional site. Patients with coagulation disorders are at greater risk.
<i>Hypovolemic shock:</i> Inadequate perfusion of tissues and cells from loss of circulatory fluid volume. Signs and symptoms are same as for hemorrhage.	In surgical patient, hypovolemic shock is usually caused by hemorrhage.
<i>Thrombophlebitis:</i> Inflammation of vein often accompanied by clot formation. Veins in legs are most commonly affected. Signs and symptoms include swelling and inflammation of involved site and aching or cramping pain. Vein feels hard, cordlike, and sensitive to touch.	Venous stasis is aggravated by prolonged sitting or immobilization. Trauma to vessel wall and hypercoagulability of blood increase risk of vessel inflammation.
<i>Thrombus:</i> Formation of clot attached to interior wall of a vein or artery, which can occlude the vessel lumen. Signs and symptoms include localized tenderness along distribution of the venous system, swollen calf or thigh, calf swelling more than 3 cm compared with asymptomatic leg, pitting edema in symptomatic leg, collateral superficial veins, and decrease in pulse below location of thrombus (if arterial).	Venous stasis (see discussion of thrombophlebitis) and vessel trauma. Venous injury is common after surgery of legs, abdomen, pelvis, and major vessels. Patients with pelvic and abdominal cancer or traumatic injuries to the pelvis or lower extremities are at high risk for thrombus formation.
<i>Embolus:</i> Piece of thrombus that has dislodged and circulates in bloodstream until it lodges in another vessel, commonly lungs, heart, brain, or mesentery.	Thrombi form with increased coagulability of blood (e.g., polycythemia and use of birth control pills containing estrogen).
Gastrointestinal System	
<i>Paralytic ileus:</i> Nonmechanical obstruction of the bowel caused by physiological, neurogenic, or chemical imbalance associated with decreased peristalsis.	Handling of intestines during surgery can lead to loss of peristalsis for a few hours to several days.
<i>Abdominal distension:</i> Retention of air within intestines and abdominal cavity during gastrointestinal surgery. Signs and symptoms include increased abdominal girth, tympanic percussion over abdominal quadrants, and patient complaints of fullness, "gas pains," and referred shoulder pain.	Slowed peristalsis from anaesthesia, bowel manipulation, or immobilization. During laparoscopic surgeries, influx of air for procedure causes distension.
<i>Nausea and vomiting:</i> Symptoms of improper gastric emptying or chemical stimulation of vomiting centre. Patient complains of gagging or feeling full or sick to stomach.	Abdominal distension, fear, severe pain, medications, eating or drinking before peristalsis returns, and initiation of gag reflex.
Genitourinary System	
<i>Urinary retention:</i> Involuntary accumulation of urine in bladder as a result of loss of muscle tone. Signs and symptoms include inability to void, restlessness, and bladder distension. It appears six to eight hours after surgery.	Effects of anaesthesia and narcotic analgesics. Local manipulation of tissues surrounding bladder and edema interfere with bladder tone. Poor positioning of patient impairs voiding reflexes.
<i>Urinary tract infection:</i> An infection of the urinary tract as a result of bacterial or yeast contamination. Signs and symptoms include dysuria, itching, abdominal pain, possible fever, cloudy urine, white blood cells, and leukocyte esterase positive on urinalysis.	Most frequently a result of catheterization of the bladder.

► TABLE 48-10 Postoperative Complications—cont'd

Complication**Integumentary System**

Wound infection: An invasion of deep or superficial wound tissues by pathogenic microorganisms. Signs and symptoms include warm, red, and tender skin around incision; fever and chills; and purulent material exiting from drains or from separated wound edges. Infection usually appears three to six days after surgery.

Wound dehiscence: Separation of wound edges at suture line. Signs and symptoms include increased drainage and appearance of underlying tissues. This usually occurs six to eight days after surgery.

Wound evisceration: Protrusion of internal organs and tissues through incision. Incidence usually occurs six to eight days after surgery.

Skin breakdown: Result of pressure or shearing forces. Surgical patients are at increased risk if alterations in nutrition and circulation are present, resulting in edema and delayed healing.

Cause

Infection is caused by poor aseptic technique or contaminated wound or surgical site before surgical exploration. For example, with a bowel perforation, the patient is at increased risk for a wound infection because of bacterial contamination from the large intestine.

Malnutrition, obesity, preoperative radiation to surgical site, old age, poor circulation to tissues, and unusual strain on suture line from coughing or positioning cause dehiscence. See discussion of wound dehiscence. Patient with dehiscence is at risk for developing evisceration.

Prolonged periods on the operating room (OR) table and in the bed postoperatively can lead to pressure breakdown. Skin breakdown results from shearing during positioning on the OR table and improper pulling of the patient up in bed.

Nervous System

Complex pain situations: These might include situations in which pain is unresponsive to standard treatment or where there are multiple sources of pain (RNAO, 2002a).

The source may be related to, for example, surgical site or concomitant injuries or pathology.

The benefits of thorough preoperative teaching are realized when patients are able to participate actively. When the patient awakens from anaesthesia, you may need to assist him or her in maintaining a patent airway. The following measures maintain airway patency:

- Position the patient on one side with the face downward and the neck slightly extended to facilitate a forward movement of the tongue and the flow of mucous secretions out of the mouth. A small folded towel supports the head. Another positioning technique to promote a patent airway involves slightly elevating the head of the bed and slightly extending the patient's neck, with the head turned to the side. The PACU nurse may need to perform a jaw thrust manoeuvre or chin lift continuously to maintain the airway in some patients. Never position the patient with arms over or across the chest because this reduces maximum chest expansion.
- Suction artificial airways and the oral cavity for mucous secretions (see Chapter 38). Care must be taken to avoid eliciting the gag reflex, which could cause vomiting. The following measures promote expansion of the lungs:
- Encourage diaphragmatic breathing exercises every hour while patients are awake. Maximal inspirations lasting three to five seconds open up alveoli.
- Instruct patients to use an incentive spirometer (if used in your hospital). The patient should try to reach the inspiratory volume achieved preoperatively on the spirometer.
- Encourage early ambulation. Walking causes patients to assume a position that does not restrict chest wall expansion and stimulates an increased respiratory rate.
- Help patients who are restricted to bed to turn on their sides every one to two hours while awake and to sit when possible. Turning permits expansion of the lungs. Sitting causes lowering of abdominal organs, thus facilitating diaphragmatic movement and lung expansion.
- Keep the patient comfortable. A patient who is comfortable will be able to participate in the postoperative regimen.

Assess, document, treat, and evaluate the patient's pain on a regular basis.

The following measures promote removal of pulmonary secretions if they are present:

- Encourage coughing exercises every two hours while patients are awake, and maintain pain control to promote a deep, productive cough. Coughing may be contraindicated for patients who have had eye or intracranial surgery because of the potential increase in intraocular or intracranial pressure.
- Provide oral hygiene to facilitate expectoration of mucus. The oral mucosa becomes dry when patients are NPO or are placed on limited fluid intake.
- Initiate orotracheal or nasotracheal suction for patients who are too weak or unable to cough (see Chapter 38).
- Administer oxygen as ordered and monitor oxygen saturation with a pulse oximeter.

Preventing Circulatory Complications.

- Measures directed at preventing circulatory complications avert circulatory stasis. Some patients are at greater risk of venous stasis because of the nature of their surgery or medical history. The following measures promote normal venous return and circulatory blood flow:
- Encourage patients to perform leg exercises at least every hour while awake. Exercise may be limited in an affected extremity involving vascular repair or realignment of fractured bones and torn cartilage.
- Apply elastic antiembolism stockings or sequential compression stockings as ordered by the physician (see Chapter 45). The antiembolism stockings should be removed at least once per shift. Perform a thorough assessment of the skin of the lower extremities at this time.
- Encourage early ambulation. Some patients are expected to ambulate on the evening of surgery, depending on the severity of the surgery and their condition. Even if a patient has an epidural catheter or a PCA device, ambulation should be encouraged. The degree of activity allowed

progresses as the condition improves. Before ambulation, you should assess the patient's vital signs. Abnormalities may contraindicate ambulation. If vital signs are at baseline, you first help the patient to sit on the side of the bed. Patient complaints of dizziness are a sign of postural hypotension. Rechecking the patient's blood pressure will help you to determine whether ambulation is safe. You assist with ambulation by standing at the patient's side and ensuring that he or she can stand safely and walk steadily. The first few times out of bed, patients may be able to walk only a few metres. This should improve each time. Evaluate tolerance to activity by periodically assessing the pulse rate as the patient ambulates.

- Avoid positioning patients in a manner that interrupts blood flow to their extremities. While in bed, patients should not have pillows or rolled blankets placed under their knees. Compression of the popliteal vessels can cause thrombi. When patients sit in chairs, their legs should be elevated on footstools. A patient should never be allowed to sit with one leg crossed over the other.
- Administer anticoagulant drugs as required. Physicians often order prophylactic doses of anticoagulants, such as heparin or Fragmin (dalteparin), for patients at greatest risk for thrombus formation.
- Promote adequate fluid intake. Adequate hydration prevents concentrated buildup of formed blood elements, such as platelets and red blood cells. When the plasma volume is low, these elements may gather and form small clots within blood vessels.

Achieving Rest and Comfort. A surgical patient's pain increases as the effects of anaesthesia diminish. The patient becomes more aware of the surroundings and more perceptive of discomfort. The incisional area may be only one source of pain. Irritation from **abdominal gas**, drainage tubes, tight dressings or casts, and the muscular strains caused from positioning on the OR table can cause discomfort.

It is common to administer narcotic analgesics immediately after surgery. Initial analgesic doses are usually given by IV infusion in the PACU and titrated to patient comfort. After an anaesthetized patient is awake and aware, PCA may be used. This is given by IV or subcutaneous infusion or via an epidural, often with Dilaudid or morphine. The PCA system allows patients to administer their own analgesics from a specially prepared pump (see Chapter 41). If patients are able to gain a sense of control over their pain, they usually have fewer postoperative problems. Gagliese et al. (2000) found that both young and older adult surgical patients were able to use PCA to attain adequate levels of pain relief. Many patients receive epidural analgesia that may be continued during the recovery period (see Chapter 41). Increasingly, patients are being prescribed more a combination of opioid and nonopioid analgesics in an effort to decrease opioid-related side effects (White, 2008) in the postoperative period. As soon as peristalsis returns, patients may be given a combination of acetaminophen and a nonsteroidal anti-inflammatory.

In the acute care area, you continue pain assessment and determine the effectiveness of interventions. Patients who will have PCA after surgery should be taught how to push the button when they begin to feel pain and they should understand that use of PCA will not cause them to overmedicate. Patients should be taught to administer PCA prior to activities that may increase pain, such as mobilization. If the patient has a PCA system and is trying to use it more frequently than

the amount programmed, you should investigate his or her pain further and contact the physician or the advanced practice nurse on the acute pain service to increase, for example, the amount of medication received. PCA provides you with a useful monitor of the effectiveness of pain medication. As oral intake is tolerated, you facilitate changing the patient's pain medication from IV to oral administration. It is important to ensure adequate pain coverage when the patient is switched from an IV to an oral route (Snell et al., 1997). Sometimes patients are given a subcutaneous injection of analgesia before transfer to the acute care area to ensure pain control over this time period. Intramuscular injections of analgesics are seldom used now. The importance of nonpharmacological interventions should not be overlooked. You should assess which care measures may contribute to pain and use nonpharmacological measures to treat it. An example would be to lower the head of the bed and use a pillow for incisional splinting while turning a patient with recent abdominal surgery. You can also use other methods of promoting pain relief, such as positioning, back rubs, distraction, or imagery. Ice packs may be ordered for patients undergoing joint replacement. Pain can slow recovery significantly. The patient becomes reluctant to cough, breathe deeply, turn, ambulate, or perform necessary exercises. You should assess the patient's pain thoroughly (see Chapter 41). You should not assume that the pain is only incisional. When the patient asks for pain medication, determine the location, intensity, and character of the pain. During the first 24 to 48 hours after surgery, you should provide analgesics on a regular basis around the clock to improve pain control (Agency for Health Care Research and Policy, 2002; RNAO, 2002a). If pain medications are not relieving discomfort, you should notify the physician or the acute pain service after completing a thorough assessment. Recognizing the potential complications of analgesics and knowing what to do if they occur is an important role of the postoperative nurse.

Acute Care

Temperature Regulation. Temperature regulation is important in the postoperative period. Patients are often cool after surgery, and the PACU nurse provides warmed blankets in the immediate postoperative period. If the patient's temperature is 35.6°C or below, a warming device such as the Bair Hugger may be used. Increasing body warmth causes the patient's metabolism to rise and circulatory and respiratory functions to improve.

Shivering may not be a sign of hypothermia but rather a side effect of certain anaesthetic agents. Meperidine (Demerol) may be given in small increments to decrease shivering. Deep breathing and coughing help to expel retained anaesthetic gases.

Malignant hyperthermia is a potentially lethal condition that can occur in patients who receive general anaesthesia (OPANA, 2009). It should be suspected when there is unexpected tachycardia and tachypnea; jaw muscle rigidity; body rigidity of limbs, abdomen, and chest; or hyperkalemia. Temperature elevation is a late sign. The PACU nurse will immediately administer dantrolene sodium ordered by the physician.

Infection is another possible cause of temperature elevation. The following interventions decrease the risk of postoperative infections: encouraging deep breathing and coughing, assisting with early ambulation, removing in-dwelling urinary catheters and IV catheters once the patient is voiding and drinking, and providing aseptic care of the surgical wound. Cultures are

obtained from patients suspected of having infections (see Chapter 46).

Maintaining Neurological Function. Orientation to the environment is important in maintaining the patient's mental status. You reorient the patient, explain that surgery has been completed, and describe procedures and nursing measures. The patient who was properly prepared before surgery is less likely to be anxious when nurses provide care. Any change in level of consciousness should be promptly reported to a physician.

Maintaining Fluid and Electrolyte Balances. An important nursing responsibility is maintaining patency and prescribed rate of IV infusions and monitoring fluid and electrolyte balances in the postoperative period. As the patient begins to take and tolerate oral fluids, the IV rate will be decreased. When an ambulatory surgical patient awakens and is able to tolerate fluids by mouth without gastrointestinal upset, the IV catheter is removed. When the patient no longer needs a continuous IV infusion, the IV line may be saline locked to preserve the site for antibiotics or other use (see Chapter 39). The patient also may receive blood products or artificial volume expanders, depending on blood loss during and after surgery.

Promoting Normal Bowel Elimination and Adequate Nutrition. Normally a patient who has had general anaesthesia does not receive fluids to drink in the PACU because of bowel sluggishness, the risk of nausea and vomiting, and grogginess from general anaesthesia. To minimize nausea, the patient should avoid sudden movement. For patients identified as being at high risk for the development of nausea and vomiting or patients who must not vomit (e.g., eye surgery), a combination of antiemetics may be recommended (Gan, 2002; Tramer, 2001). If the patient has a nasogastric tube, you check the position of the tube and ensure patency by observing for drainage. If suction is required, you verify that it is maintained at the required level (see Chapter 44). Occlusion of a nasogastric tube results in accumulation of gastric contents within the stomach.

The patient likely will begin taking ice chips or sips of fluids once he or she is returned to the acute care unit. If these are tolerated, a clear liquid meal usually will be ordered. Interventions for preventing gastrointestinal complications promote return of normal elimination and faster return of normal nutritional intake. It takes several days for a patient who has had surgery on gastrointestinal structures (e.g., a colon resection) to resume a normal diet. Normal peristalsis may not return for two to three days. In contrast, the patient whose gastrointestinal tract is unaffected directly by surgery can resume dietary intake after recovering from the effects of anaesthesia. The following measures promote return of normal elimination:

- Maintain a gradual progression in dietary intake. For the first few hours after surgery, a patient receives only IV fluids. If bowel sounds are active and the physician orders a normal diet for the first evening after surgery, begin by providing clear liquids, such as water, ginger ale, broth, or tea, after nausea subsides. Overloading the patient with large amounts of fluids may lead to distension and vomiting. If the patient tolerates liquids without nausea, advance the diet as ordered. Patients who have had abdominal surgery are usually NPO for the first 24 to 48 hours after the procedure. As peristalsis returns, provide clear liquids, followed by full liquids, a light diet of solid foods, and

finally the patient's usual diet. Encourage intake of foods high in protein and vitamin C.

- Promote ambulation and exercise. Physical activity stimulates a return of peristalsis. The patient who suffers abdominal distension and "gas pain" may obtain relief while walking.
- Maintain an adequate fluid intake. Fluids keep fecal material soft for easy passage. Fruit juices and warm liquids are especially effective.
- Administer fibre supplements, stool softeners, and rectal suppositories such as Dulcolax (bisacodyl) as ordered. If constipation or distension develops, the physician may attempt to stimulate peristalsis with cathartics or enemas, but caution must be exercised.
- Promote adequate food intake by stimulating the patient's appetite:
 - Remove sources of noxious odours and provide small servings of nonspicy foods.
 - Assist the patient to a comfortable position during mealtime. The patient should sit if possible to minimize pressure on the abdomen.
 - Provide desired servings of food. For example, a patient may be more willing to face his or her first meal when servings are not large.
 - Provide frequent oral hygiene. Adequate hydration and cleansing of the oral cavity eliminate dryness and bad tastes.
 - Provide meals when the patient is rested and free from pain. Often a patient loses interest in eating if mealtime has been preceded by exhausting activities, such as ambulation, coughing and deep breathing exercises, or extensive dressing changes. When a patient has pain, the associated nausea often causes a loss of appetite.

Promoting Urinary Elimination. The depressant effects of anaesthetics and analgesics impair the sensation of bladder fullness. If bladder tone is reduced, the patient has difficulty starting urination. However, patients should void within 8 to 12 hours after surgery. Because a full bladder can be painful and often causes restlessness in recovery, it may become necessary to insert a catheter. If the patient has an in-dwelling urinary catheter, the goal should be to have it removed as soon as possible because of the high risk for development of a nosocomial bladder or urinary tract infection.

Patients who undergo surgery of the urinary system frequently have an in-dwelling urinary catheter inserted to maintain free urinary flow until voluntary control of urination returns. The following measures promote normal urinary elimination (see Chapter 43):

- Help the patient to assume normal positions during voiding. The male patient may need assistance to stand to void. Bedpans make voiding difficult. A female patient will have better results if she is able to use a toilet or a bedside commode.
- Check the patient frequently for the need to void. A surgical patient restricted to bed needs assistance in handling and using bedpans or urinals. Often the patient acquires a sudden feeling of bladder fullness and urgency to void and will need help quickly.
- Assess for bladder distension. If a patient does not void within eight hours of surgery or if bladder distension is present, it may be necessary to insert a straight in and out urinary catheter. A physician's order is needed for this. Continued difficulty in voiding may require an in-dwelling

catheter, although the risk for a urinary tract infection increases.

- Monitor intake and output. Urine output should be at least 30 mL/hour for adults. If the urine is dark, concentrated, and low in volume, the physician should be notified. A patient can easily become dehydrated as a result of fluid loss from the surgical wound. Measure intake and output for several days after surgery until normal fluid intake and urinary output are achieved.

Promoting Wound Healing. A surgical wound undergoes considerable stress during convalescence. The stress of inadequate nutrition, impaired circulation, and metabolic alterations increases the risk for delayed healing (see Chapter 46). A wound also may undergo considerable physical stress. Strain on sutures from coughing, vomiting, distension, and movement of body parts can disrupt the wound layers. You protect the wound and promote healing. A critical time for wound healing is 24 to 72 hours after surgery, after which time a seal is established. If a wound becomes infected, it usually occurs three to six days after surgery. A clean surgical wound usually does not regain strength against normal stress for 15 to 20 days after surgery. You must use the aseptic technique during dressing changes and wound care (see Chapters 32 and 46). Surgical drains must remain patent so that accumulated secretions can escape from the wound bed. Ongoing observation of the wound identifies early signs and symptoms of infection.

Maintaining and Enhancing Self-Concept. The appearance of wounds, bulky dressings, and extruding drains and tubes threatens a patient's self-concept. The effects of surgery, such as disfiguring scars, may create permanent changes in the patient's body image. If surgery leads to impairment in body function, the patient's role within the family can change significantly.

You should observe patients for alterations in self-concept. Patients may show revulsion toward their appearance by refusing to look at incisions, carefully covering dressings with bedclothes, or refusing to get out of bed because of tubes and devices. The fear of not being able to return to a functional role in their families may cause patients to avoid participating in the care plan.

The family becomes an important part of efforts to improve the patient's self-concept. You explain the patient's appearance to the family and suggest ways to avoid nonverbal expressions of revulsion or surprise. The family needs to be accepting of the patient's concerns and encourage the patient's independence. If the condition is permanent, the family and patient will go through a grieving process. Coping strategies develop over time to manage the situation. The following measures help to maintain the patient's self-concept:

- Provide privacy during dressing changes or inspection of the wound. Keep room curtains closed around the bed, and drape the patient so that only the dressing or incisional area is exposed.
- Maintain the patient's hygiene. Wound drainage and antiseptic solutions from the surgical skin preparation dry on the patient's skin surface and cause irritation. When patients return to the unit, they should be given a postoperative bath and provided oral hygiene. In addition, a complete bath on the first day after surgery can make the patient feel renewed. When the patient's gown becomes soiled by wound drainage, offer a clean gown and washcloth. Keep the patient's

hair clean and neatly combed. Offer frequent oral hygiene. Room deodorizers may be useful if the odour from drainage seems particularly troublesome to the patient and the family.

- Prevent drainage devices from overflowing. Contents of drainage collections are measured every 8 hours or 12 hours for output recording and are emptied as they become full. The patient sometimes becomes preoccupied with observing the gradual collection of drainage, and some drainage devices can leak contents if they become too full.
- Maintain a pleasant environment. Self-concept is heightened by the patient being in pleasant, comfortable surroundings. Store or remove unused supplies and keep the patient's bedside orderly and clean.
- Offer opportunities for the patient to discuss feelings about his or her appearance. A patient who avoids looking at an incision may need to discuss fears or concerns. A patient having surgery for the first time is often more anxious than one who has had multiple surgeries. When the patient chooses to look at an incision for the first time, the area should be clean. Eventually, the patient should be able to care for the incision site by applying simple dressings or cleaning the affected area.
- Provide the family with opportunities to discuss ways to promote the patient's self-concept. Encouraging independence can be difficult for a family member who has a strong desire to assist the patient in any way. By knowing about the appearance of a wound or incision, family members can be supportive during dressing changes. The topic or tone of a conversation can also help family members support a patient who is dwelling on fears and concerns. Family members should not avoid discussing the future. However, they need help to know when it is appropriate to discuss future plans. Then the patient and family can work together to discuss realistic plans for the patient's return home.

Restorative and Continuing Care

You, the patient, and the family work to prepare the patient for discharge. Education regarding wound care, activity level, diet, medications, and specifics related to the type of surgery is an ongoing process throughout hospitalization. After discharge, some patients will need assistance from home care services with tasks such as wound care (Box 48-8). With ambulatory surgery patients, focused education within the limited time is essential. Including the family or a significant other person provides a resource for the patient once he or she is at home (see Box 48-6). With both ambulatory and hospitalized surgical patients, nurses provide a wide variety of written educational materials. For example, educational materials with many pictures should be used with patients who do not speak your language or who have limited reading ability. Materials should be sensitive to various cultures and religions. However, the provision of materials does not ensure understanding. Verification, return demonstration, and ongoing clarification are required.

Evaluation

Patient Care

You evaluate the effectiveness of care provided to the surgical patient on the basis of expected outcomes after nursing interventions. In all surgical settings, you consult with the patient

* BOX 48-8

FOCUS ON PRIMARY HEALTH CARE

Recovery at Home

Regardless of the length of time the patient spends in hospital, it is essential that you ensure that the patient and family have the appropriate information and skills needed to continue a successful recovery at home. However, time is often very limited, especially with the move toward preadmission units and short hospital stays. A comprehensive approach is needed to ensure continuity of care from hospital to home. A patient is often expected to continue dressing care, follow activity restrictions, continue medication therapy, and observe for signs and symptoms of complications upon returning home. In addition, the patient needs someone to be present for the first 24 hours to ensure that no delayed reaction from the anaesthesia occurs, such as difficulty breathing. A referral to home care assists patients who are unable to perform self-care activities. Close association with home care services is required for some patients if dressing changes or physiotherapy is needed. It is useful to have a case management nurse in attendance at discharge to convey what tasks a patient can perform effectively.

and the family to gather evaluation data. You can evaluate the ambulatory surgical patient's outcomes via a telephone call to the patient's home, asking specific questions to determine whether complications have developed and whether the patient understands restrictions or medications. This call is usually placed 24 hours after surgery, which allows you to evaluate the progress of recovery.

In an acute care setting, evaluation of a surgical patient is ongoing. If a patient fails to progress as expected, you revise the patient's care plan according to the priorities of the patient's needs. Every effort is made to assist the patient in returning to as healthy and functional a state as possible. Your evaluation also includes determining the extent to which the patient and the family have learned self-care measures.

Patient Expectations

With short hospital stays and ambulatory surgery, it is especially important to evaluate patient expectations early in the postoperative process. Pain relief is usually a priority. Asking the patient if everything possible has been done to alleviate pain, including nonpharmacological measures, can determine whether the patient's needs have been met. Timeliness of response to the patient's needs, such as scheduled times for pain medication and prompt answering of a call light, may increase satisfaction. The patient usually wants to be discharged from acute care as soon as possible and when indicated by the physician. Ensuring that discharge plans are in place facilitates that process and enhances the patient's satisfaction with care.

* KEY CONCEPTS

- Perioperative nursing is nursing care provided to the surgical patient before, during, and after surgery.
- Surgery is classified by level of severity, urgency, and purpose.
- The preoperative period may be several days or only a few hours long.

- Preoperative assessment of vital signs and physical findings provides an important baseline with which to compare postoperative assessment data.
- Nursing diagnoses of the surgical patient may pose implications for nursing care during one or all phases of surgery.
- Primary responsibility for obtaining informed consent rests with the patient's surgeon.
- Structured preoperative teaching has a positive influence on a patient's postoperative recovery.
- Basic to preoperative teaching is an explanation of all preoperative and postoperative routines and demonstration of postoperative exercises.
- In ambulatory surgery, nurses must use the limited time available to educate patients, assess their health status, and prepare them for surgery.
- A routine preoperative (preprocedure) checklist can be used as a guide for final preparation of the patient before surgery.
- Many responsibilities of nurses within the OR focus on protecting the patient from potential harm.
- All medications taken before surgery are automatically discontinued after surgery unless a physician reorders the drugs.
- Family members or other supportive networks are important in assisting patients with any physical limitations and in providing emotional support during postoperative recovery and ongoing care at home.
- Assessment of the postoperative patient centres on the body systems most likely to be affected by anaesthesia, immobilization, and surgical trauma.
- Accurate pain assessment and intervention are necessary for healing.
- Nurses in the postoperative surgical unit provide the discharge education required so that the patient and the family can manage at home.

* CRITICAL THINKING EXERCISES

1. An 82-year-old patient is admitted for surgery on a fractured hip caused by a fall. What postoperative complications are typical in the older patient undergoing this type of surgery?
2. Mr. B. is a 52-year-old patient who will undergo thoracic surgery. He has smoked one pack of cigarettes per day for 30 years. What type of pulmonary preventive measures would you expect Mr. B. to need postoperatively?
3. Mrs. C. was admitted for same-day surgery for an inguinal hernia repair. What discharge criteria would be used for Mrs. C., and what discharge instructions would she require?
4. Your patient is scheduled for abdominal hysterectomy at 2:00 P.M. Based on NPO guidelines, what fasting schedule should you implement in collaboration with the surgeon and the anaesthesiologist?
5. You are doing preoperative teaching for a patient undergoing a minimally invasive surgical technique. Identify one advantage of this type of surgery.

* REVIEW QUESTIONS

1. An obese patient is at risk for poor wound healing and for wound infection postoperatively because
 1. Ventilatory capacity is reduced
 2. Fatty tissue has a poor blood supply
 3. Risk for dehiscence is increased
 4. Resuming normal physical activity is delayed

2. You should ask each patient preoperatively for the name and dose of all prescription and over-the-counter medications taken before surgery because they
 1. May cause allergies to develop
 2. Are automatically ordered postoperatively
 3. May create greater risks for complications or interact with anaesthetic agents
 4. Should be taken on the morning of surgery with sips of water
3. A patient who smokes two packs of cigarettes per day is most at risk postoperatively for
 1. Infection
 2. Pneumonia
 3. Hypotension
 4. Cardiac dysrhythmias
4. Family members should be included when you teach the patient preoperative exercises so that they can
 1. Supervise the patient at home
 2. Coach the patient postoperatively
 3. Practise with the patient while waiting to be taken to the operating room
 4. Relieve you by getting the patient to do his or her exercises every two hours
5. In the postoperative period, measuring input and output helps assess
 1. Renal and circulatory function
 2. Patient comfort
 3. Neurological function
 4. Gastrointestinal function
6. In the PACU, one measure taken to maintain airway patency is to
 1. Suction the pharynx and bronchial tree
 2. Give oxygen through a mask at 10 L/minute
 3. Position the patient so that the tongue falls forward
 4. Sit patient in high-Fowler's position
7. Which one of the following measures promotes normal venous return and circulatory blood flow?
 1. Suctioning artificial airways and the oral cavity
 2. Monitoring fluid and electrolyte status during every shift
 3. Having the patient deep breath and cough
 4. Encouraging the patient to perform leg exercises at least once an hour while awake
8. A patient with an international normalized ratio (INR) or an activated partial thromboplastin time (APTT) greater than normal is at risk postoperatively for
 1. Anemia
 2. Bleeding
 3. Infection
 4. Cardiac dysrhythmias
9. When the patient is engaging in deep breathing and coughing exercises, it is important to have the patient sitting because this position
 1. Is more comfortable
 2. Facilitates expansion of the thorax
 3. Increases the patient's view of the room and is more relaxing
 4. Helps the patient to splint with a pillow
10. In the postoperative period, if a patient has unexpected tachycardia and tachypnea; jaw muscle rigidity; body rigidity of limbs, abdomen, and chest; or hyperkalemia, you should suspect
 1. Infection
 2. Hypertension
 3. Pneumonia
 4. Malignant hyperthermia

✦ RECOMMENDED WEB SITES

Canadian Anesthesiologists' Society: <http://www.cas.ca>

This Web site offers patient information about and guidelines for using anaesthesia.

National Association of PeriAnesthesia Nurses of Canada: <http://www.napanc.org>

Perianaesthesia nurses are registered nurses with advanced knowledge in the care of patients during all phases of perianaesthesia, including, for example, nurses in postanesthesia care units, same-day surgery, and diagnostic imaging.

Operating Room Nurses Association of Canada: <http://www.ornac.ca>

This Web site provides practice standards for Canadian operating room nurses, as well as information on certification with the Canadian Nurses Association (CNA).

Ontario PeriAnesthesia Nurses Association: <http://www.opana.org>

This Web site provides position statements on and standards of perianaesthesia nursing practice.

Appendix A Practical Nursing in Canada

Written by Barb Morrison, RN, BScN, MEd

objectives

Mastery of content in this appendix will enable you to:

- Define the key terms listed.
- Explain how practical nursing has evolved as a regulated nursing group in Canada.
- Discuss the current issues and trends that affect practical nurses in Canada.
- Differentiate the scope of practice of the practical nurse from that of the RN and unregulated health care provider.
- Explain how legislation, regulatory bodies, and professional associations govern the practice of practical nurses.
- Predict the future role of practical nurses within the Canadian health care system.

History of Practical Nursing in Canada

Practical nursing is the second-largest regulated nursing group in Canada. It has a relatively short history, having become a profession only in the late 1930s. Initially beginning as a hands-on, hospital-based program with few common standards and little legislative control, practical nursing has evolved into a profession that requires a sound knowledge base and is publicly accountable under legislative control.

The Beginnings of Practical Nursing

In some respects, practical nursing has always existed. Whenever people have provided “hands-on” nursing care, they have been providing practical nursing care. Only since the 1970s, however, has practical nursing been

recognized as a distinct profession that necessitates formal education. Until about the mid-1970s, only minimal high school preparation was necessary for entry into a practical nursing program, and the program was most often a short apprenticeship in a hospital setting. No licensure examination was required. Also, no official **registration**, **protected title**, or professional body existed.

The Evolution of Practical Nursing

Practical nursing has evolved in a similar way in most provinces. It has also followed a similar pattern that other occupations have followed when they are established as professions. Abbott (1988) studied 130 occupations and noted that as they evolve into professions, the following characteristics are developed:

1. A national professional association
2. Government-sponsored licensing legislation
3. Professional examinations
4. A professional school separate from schools for other professions
5. A university-based professional education
6. A code of ethics
7. A national-level journal
8. An accreditation program (in the United States) or a certification program (in the United Kingdom)

Except for university-based education requirements and a national-level journal, practical nursing has established all the other steps. Abbott (1988), however, did not note the series of name and designation changes that seem to be unique to practical nursing, nor did his list highlight the tendency to require increasing levels of education, which some authorities have termed "**creeping credentialism**."

Canada. As early as 1914, the Canadian National Association for Trained Nurses (called the Canadian Nurses Association [CNA] since 1924) recognized the value of practical nursing, especially for providing care to patients in the home (College of Licensed Practical Nurses of British Columbia [CLPNBC], 2011). The first **practical nurses** were usually called either nursing aides (if female) or orderlies (if male).

In 1931, practical nurses in Canada numbered 4700. By 1947, this statistic had increased to more than 7900, largely because of increased hospital service needs after the Second World War. The first formal education program specifically for practical nurses (as opposed to nursing aides or orderlies) began in Manitoba in 1945 (Canadian Institute for Health Information [CIHI], 2010; College of Licensed Practical Nurses of British Columbia [CLPNBC], 2011, p. 81). The first legislative acts controlling the education, testing, licensing, regulation, and practice of practical nursing were introduced in the 1940s.

Over the years, practical nursing in Canada has undergone many changes in designation, as well as function. Practical nurses have struggled to achieve self-regulation, rather than government regulation, of their profession.

Many of the changes in the education of the practical nurse reflect the same changes that occurred earlier in the education of the registered nurse (RN). Practical nurses are required to obtain higher levels of education. Education programs have become longer and more complex and have moved from hospital schools to postsecondary institutions, such as colleges. Rather than continuing to emphasize tasks and procedures, education programs have begun to focus more on holistic principles of nursing.

In the 1980s, most provinces developed regulations to govern practical nursing and were requiring graduates to write a licensing examination provided by what was then the Canadian Nurses Association Testing Service (CNATS). Graduates of practical nursing programs across Canada (except in Quebec) now must pass a national registration examination before they can begin professional practice. (Quebec has its own practical nursing examination.)

Table A-1 presents historical highlights in the evolution of practical nursing in selected provinces.

United States. In the United States, the first official practical nurse program was started by the Ballard School in New York in 1893, with a three-month course to train women in simple nursing care, home care, and cooking (Hill & Howlett, 2005).

US nurses were the first to use the term *licensed practical nurse (LPN)*, setting a precedent that many Canadian provinces and territories have since followed.

United Kingdom. Before the early 1990s, nursing education in the United Kingdom was provided in nursing schools attached to hospitals. Project 2000, started in the early 1990s in the United Kingdom, aimed to increase the professional stature of nursing by removing it from its hospital service base and placing it in postsecondary educational institutions. Today, nursing education in the United Kingdom, as in Canada and the United States, takes place in the postsecondary school system at the college or technical school level (NursingNetUK, n.d.). Courses in enrolled nursing (the closest equivalent to practical nursing) no longer officially exist. Therefore, practical nurses from other countries cannot be certified in nursing in the United Kingdom unless they undergo upgrading.

The Demand for Practical Nursing

In the late 1940s and early 1950s, demand for practical nurses increased significantly in most jurisdictions. A number of factors were responsible for this increased demand, including political and economic pressures, changes within the nursing profession, and ecological and sociological factors.

Political and Economic Pressures. As roles for women expanded after the Second World War and more opportunities were available in a range of occupations and professions, the number of nurses decreased. This shortage of registered nurses came at a time when patients' **acuity** (i.e., their level of sickness) was increasing in institutions. In addition, an increasing aged population was requiring more supportive care in communities and long-term care facilities, and private enterprise began exerting a greater economic influence on health care.

Because this public demand for safe and competent practice increased at the same time as economic and personnel challenges, practical nursing became more important within the health care system. Practical nursing offered an economical but highly competent workforce to meet the needs of patients in hospitals and those requiring long-term care.

Changes Within Nursing

Nursing Education. The changing methods of educating nurses also contributed to the personnel and economic challenges in the health care sector. For many years, hospitals and other health care agencies depended on nursing students for the free staffing of their institutions. When nursing education moved from a hospital base to a postsecondary base (beginning in the early 1970s), the number of available staff decreased suddenly. Institutions responded by employing

TABLE A-1
History of Practical Nursing in Selected Provinces

Province	Year	Significant Developments and Comments
British Columbia (BC)	1951	<i>Practical Nurse Act</i> passed
	1965	<i>Practical Nurses' Act</i> legally approved
		Council of LPNs established as the licensing body
	1991	Council of LPNs becomes an independent regulatory body of the Ministry of Health
Alberta	1996	The Council of LPNs in BC becomes the College of LPNs of B.C. under <i>Health Professions Act</i>
	1945	The School for Nursing Aides established in Calgary, sponsored by Department of Veterans Affairs and Canadian Vocational Training
	1947	<i>The Provincial Nursing Aides Act</i> passed, allowing licensing of the Certified Nursing Aide
	1961	Alberta Certified Nursing Aide Association (ACNAA) incorporated
	1972	Alberta Certified Nursing Aide Association, along with eight other practical nursing associations, becomes a founding member of the Canadian Association of Practical Nurses and Nursing Assistants
	1978	<i>Nursing Assistant Registration Act</i> combines aide and orderly in one category of RNA (registered nursing assistant)
	1987	Professional Council of RNAs (PCRNA) becomes first health care discipline under <i>Health Disciplines Act</i> . Registered nursing assistants become self-regulatory with a distinct scope of practice.
		Nursing assistant graduates required to write <i>Canadian Practical Nurse Registration Examination</i> (national licensing examination)
	1990	RNAs change title to LPNs
		Professional Council of RNAs becomes Professional Council of LPNs
	1995	Mandatory educational upgrading instituted as a result of LPN devaluation and membership decline
	1998	Council changes its name to College of Licensed Practical Nurses of Alberta
	1999	<i>Health Disciplines Act</i> becomes <i>Health Professions Act</i> , which will eventually include all regulated health care professions under their separate provincial colleges
	2003	The College of Licensed Practical Nurses of Alberta is formally proclaimed
	2004	LPNs in specialized practice are recognized by the <i>Health Professions Act</i>
	2006	Diploma is approved as the entry-to-practice requirement
	2009	Number of Alberta LPNs doubles between 1999 and 2009
Manitoba	1945	First official practical nurse education program in Canada
Ontario	1938	Centres begin offering six-month courses for nursing assistants
	1941–1945	With approval of Ontario Department of Health, Registered Nurses Association of Ontario (RNAO) sponsors eight six-month training programs for nursing assistants
	1947	<i>Nurses Act</i> is amended to allow title of Certified Nursing Assistant (CNA)
	1963	CNA title is changed to Registered Nursing Assistant (RNA)
	1990	RNA training programs moved to community colleges
	1993	RNA title is changed to Registered Practical Nurse (RPN)
	2001	College of Nurses of Ontario passes a regulation to require all RPNs to obtain their basic diploma through an enhanced two-year program in a provincial college as an entry-to-practice requirement beginning January 2005
	2002	All practical nursing programs were offered in colleges
	1977	Legislature established an act of incorporation, giving the Association of New Brunswick Registered Nursing Assistants the responsibility of education, registration, and discipline of registered practical nurses
	1987 and 2000	Unsuccessful attempts to change the RNA title to Licensed Practical Nurse through the New Brunswick Legislature
New Brunswick	2002	The Licensed Practical Nurses Act recognizes the new LPN title
		The Association of New Brunswick Licensed Practical Nurses becomes the name of the provincial association

Data from College of Licensed Practical Nurses of British Columbia (2009, 2011), College of Licensed Practical Nurses of Alberta (2011), Canadian Institute for Health Information (CIHI, 2010, p. 81), Registered Practical Nurses Association of Ontario (2011a, pp. 1, 2), and Association of New Brunswick Licensed Practical Nurses (2011).

greater numbers of poorly trained health care assistants (i.e., **unregulated care providers**) to provide basic care. This reliance on a less trained workforce has not always benefited the public, who demand accountability and professionalism in health care. Increased public demand has resulted in higher standards and legal licensing requirements for all categories of nurse, including the practical nurse.

Registration Laws. The introduction of registration requirements for RNs also influenced the practical nurse.

Nurse registration laws in the earlier part of the twentieth century protected the title of “registered nurse”; however, they could not control other forms of nonregistered nursing. As long as unregulated care providers did not claim to be registered, they could still practise many nursing activities. This enabled agencies to save money by hiring these less expensive but less qualified workers.

After the Second World War, the public began demanding more qualified practitioners. As a result, nurse registration

laws were amended to allow the creation of another level within nursing practice. Most provinces now have two categories of nurses: (1) registered nurses (including nurse practitioners), and (2) practical nurses. A nurse in the practical nurse category can use the title "registered practical nurse" (RPN) or "licensed practical nurse" (LPN), depending on the provincial or territorial regulatory body. In the four western provinces, a third category exists: registered psychiatric nurses (also referred to as RPNs).

Development of Categories within the Nursing Profession. As noted previously, Canadian nursing has evolved into two categories of professional practitioners (and in the four western provinces, three): registered nurses and practical nurses. In comparison with the nursing profession, the medical profession essentially has one level of practitioner (a medical doctor) and many subspecialties (e.g., pediatrics, ophthalmology, orthopedics, and so on). Medical doctors also cede limited activities to other professions while maintaining their own professional position. For example, ophthalmologists (medical doctors specializing in vision disorders) are authorized to measure vision and prescribe corrective lenses. However, their practice involves many more responsibilities than these two simple functions. Therefore, they cede these two functions to optometrists. Optometrists have a unique, limited scope of practice and make no claims to be medical doctors. In the United States and Canada, some doctors also have physician's assistants to perform limited tasks. Like optometrists, these workers do not claim to be medical doctors.

Between the medical profession and its various offshoots, it can thus be seen that the boundaries of practice are quite distinct. Medicine has retained the central tasks of diagnosis and treatment of human disease states, functions that are clear in the public mind. Nursing, however, has developed a much less definitive practice, dividing the professional knowledge base and functions somewhat less clearly and neatly. Basic theory and practice are common to both categories of nurses, which are divided only by depth of knowledge and complexity of care required. However, patient complexity, predictability, and stability are hardly absolute. They are easily changeable and can be difficult to define. As a result, practitioners and the public are sometimes unsure about the boundaries between registered and practical nurses.

Exploring the theories of ecology and sociology as they apply to nursing can offer further insights into the development of two categories of nursing. These theories consider reactions to change and competition among groups for functions, power, rewards, and even professional survival.

Ecological and Sociological Factors

Ecology Theory Applied to Nursing. Ecology theory in general describes changes in populations resulting from environment and evolution. Ecology theory originally referred only to plants and animals, but some authorities have expanded it to apply to social groups such as companies and professions (Wilson, 1992).

In order to survive, groups must (1) compete for niches (places or functions in any system) and (2) evolve to cope effectively with environmental changes. Groups that have too narrow a function or who fail to compete successfully lose their niche to other groups. Niches may also change; therefore, successful adaptation requires either competing for a new niche or acquiring the niche first and establishing a solid place in it.

Two concepts in biological evolution that can be applied to practical nursing are the concepts of **speciation** and

hybridization. In *speciation*, the species divides into one or more subspecies, each with its own particular function or niche. In *hybridization*, the new species adopts characteristics of one or more of the ancestor species (Van House & Sutton, 2000).

If the concept of speciation is applied to nursing, it is apparent that the functions of the "species" of nurses have evolved. Out of the single species, two "subspecies" have arisen: the registered nurse (who usually has a university degree and is educated to cope with a wide variety of patient [environmental] challenges) and the practical nurse (who has a college diploma and is educated to cope with a limited variety of patient challenges). Some provinces also have a third "subspecies," the registered psychiatric nurse, who has a college education and is trained to provide care to patients with mental illness. The niche for the registered nurse is wider than that of the practical nurse, and the niche for the registered psychiatric nurse is the narrowest of all.

The concept of hybridization can also be applied to nursing. Nursing has adopted characteristics of other "species"; in particular, it has adopted ideas and technology that have previously been exclusively medical functions. For example, taking blood pressure, starting intravenous infusions, and making certain types of diagnoses are now nursing functions that used to be medical functions.

It is interesting that whereas nursing has developed speciation, medicine has avoided speciation and instead developed **specialization**. Where nurses share functions, doctors cede specific unwanted functions to different professionals. The sharing of functions among practical and registered nurses is what contributes to the public and professional confusion about the roles of the two levels of nurses.

Sociology Applied to Nursing. Sociology is the study of group roles, functions, and interactions. Abbott's (1988) unique theory about professions can be melded with ecology theory to provide more insight into the development of professions. According to Abbott, a profession attempts to keep certain tasks or problems for itself and shares them with others only if it can do so without endangering its own niche.

Abbott (1988) also believed that a profession protects itself and its niche position by possessing a sound knowledge base. In other words, acquiring knowledge is central to developing a strong professional identity. Abbott believed that knowledge sets a true profession apart from a mere occupation:

Practical skill grows out of an abstract system of knowledge and control of the occupation lies in control of the abstractions that generate the practical techniques ... Any occupation can obtain licensure (e.g., beauticians) or develop an ethics code (e.g., real estate). But only a knowledge system governed by abstractions can redefine its problems and tasks, defend them from interlopers, and seize new problems ... Abstraction enables survival in the competitive system of professions. (p.8)

Professional tasks are either objective (knowledge and technology based) or subjective (culturally or legally based) in nature. Some objective tasks unique to nursing have been the development of the nursing process and nursing diagnoses. Subjective tasks are most clearly seen in the legal criteria for nursing defined in each province. For example, the *Ontario Regulated Health Professions Act* defines three authorized (controlled) acts that may be performed by nurses in that province: performing a procedure below the dermis or mucous

membrane; placing an instrument, hand, or finger into a body opening; and administering a substance by injection or inhalation. Of course, much overlap exists; that is, the authorized nursing acts in Ontario are based on both knowledge and technology and are legally defined (College of Nurses of Ontario [CNO], 2009a).

Objective tasks are more resistant to change than are subjective tasks. Environment often brings in new tasks, new knowledge, and new technology. The successful profession adopts the knowledge and new tasks it wants, strives to maintain current knowledge and tasks it considers worth keeping, and works to prevent other professions from intervening in its acquired knowledge and task base (its ecological niche). A successful profession is supported in this by subjective forces from the environment, such as legal sanctions, public opinion, and workplace practices and rules, all of which reflect the culture and the society.

Practical nursing has had mixed success in these areas. Most jurisdictions have enacted definitive legal supports (such as registration, licensing, and protected title) for a particular knowledge base and specified range of tasks. However, practical nurses still strive to clarify their role for both the public and the government. Their knowledge and practice are very similar to those of registered nurses (varying only in depth and skill level, as noted previously). The workplace in many provinces is also challenged to make appropriate use of the practical nurse's skills in many areas, avoiding either underuse or exploitation of the practical nurse's knowledge and skill set:

Abbott's [1988] analysis also casts light on the debate raging in most professional schools—what is the perfect balance between theory and practice? A student focusing solely on theory (or the abstract knowledge base) lacks the skills and tools to practice the profession; however, Abbott [warned] that practice-based knowledge lacks abstraction. An exclusive focus on the tools and service models leaves the student with no ability to extend the underlying knowledge base to new niches. In times of rapid change in niches, a thorough understanding of the knowledge base, not simply the tools and skills, is most likely to provide safe passage to the new environment. (Van House & Sutton, 2000, p. 60)

Practical nurses in Canada are striving to achieve a balance in both theory and practice. Basic education is increasing in complexity and promoting the concept of lifelong learning for the professional. In addition to basic education, many practical nurses complete **credentialling** in specialty areas after graduation, which enhances the individual's knowledge base and adaptive ability and increases professional credibility in the public mind.

Failure to adapt to changes can result in a loss of niche, role, and position. A profession could become like the panda, endangered because it has an extremely narrow niche in the ecosystem and is unable to adapt to the changing environment (Van House & Sutton, 2000). On the other hand, having a niche that is too broad could result in the profession's loss of political (public, governmental, and interprofessional) support. Too much knowledge or task sharing between specific niches (blurred boundaries) could also threaten survival of a professional species.

We have addressed some reasons for the development of practical nursing as a unique profession and provided some theoretical insights. However, why distinct levels (or species) have developed within nursing is still unanswered. It remains to be seen whether this division of professional nursing into

two (and three) levels of practitioner will strengthen or weaken nursing as a profession and preserve its position in the health care system.

Practical Nursing Today: Issues and Trends

Like other evolving professions, practical nurses face many issues and trends pertaining to their educational requirements and clinical roles. Many of the same issues and trends are apparent across the country.

Educational Preparation

Patients' needs are becoming ever more complex. Practical nurses must respond to increased acuity, wide cultural and social variations among patients, and a continuing trend toward home and community care. As the practice environment for practical nurses changes, national entry-to-practice competencies are reviewed and revised (as of this writing, the most recent changes occurred in 2011 [Assessment Strategies Inc., 2011]). Practical nursing education has become more demanding as programs strive to prepare practical nurses to meet these changing requirements at the entry level. Most programs include strong theory and practical hands-on components, as well as clinical consolidation and preceptorship experiences before graduation.

Entry to a Practical Nurse Program. Entry requirements for practical nursing programs have become more stringent. At one time, only a Grade 9 or 10 level of education was required for entry into a practical nursing school. Now, Canadian practical nursing programs require that applicants have a high school diploma. Most require that they also have high marks in language and in one or two sciences. Many postsecondary institutions also admit mature students without a high school diploma if they can demonstrate equivalent learning through other forms of education or can successfully complete mature student testing.

Location and Length of Program. In most Canadian jurisdictions, practical nursing programs are diploma programs that run for two academic years (approximately four semesters) and are offered in postsecondary institutions. In order to facilitate student access to nursing education, some educational institutions are offering practical nursing programs by nontraditional delivery methods such as distance education and online learning. The CIHI (2010) reported that in 2009, 97.5% of practical nurses in all provinces and territories possessed an initial diploma or certificate level of education or equivalent (p. 81). The programs commonly require two years in order to address the complexity of the patient base and the need for knowledgeable and flexible professional care.

Instructors in Practical Nursing Programs. Canadian nursing instructors are usually required to have clinical experience and educational preparation that is at least one level beyond that of their students. At one time, this meant that registered nurses taught aides and practical nurses. Today, almost without exception, registered nurses with baccalaureate degrees teach in practical nursing programs. Many have master's degrees or doctorates in nursing, education, or other related areas.

Registered nurses and practical nurses are most often involved with teaching students in the clinical area. These clinical teachers may be hired directly by a postsecondary

institution or may be employees of the agency in which clinical practice takes place. Teaching models vary; some programs employ practical nurses as course instructors, and others employ them as assistants under the direction of a lead course instructor. Practising LPNs also serve as role models and support students educationally during preceptorship experiences.

Student Clinical Practice. The practical nurse can work in many clinical settings. Securing appropriate clinical placements for students is a challenge in some provinces, for two main reasons:

1. Some acute care areas (e.g., surgery, acute medicine, and pediatric wards) either do not use or limit the use of practical nurses in patient care. Even though documented professional standards indicate that practical nurses are qualified to work in such areas, many institutional bureaucracies and individual staff either are unfamiliar with new standards or feel personally and legally uncomfortable with them.
2. Many areas are inundated with requests for clinical placements of students from various health care fields, often at the same time. This problem is especially prominent in the larger urban centres, where many university and college health care students compete for clinical placements. Not having appropriate clinical placements is a serious issue for students. Practical nursing students need to be placed in clinical settings in which they can work to their full scope of practice. If they do not have this opportunity, their educational experience suffers. To address these challenges, practical nursing programs are incorporating innovative approaches to better prepare their students for clinical placements and to maximize the quality of their clinical experiences. Many schools are integrating the use of "computerized human patient simulators" and clinical simulations in order to increase student confidence and enhance readiness to practise before clinical practicum experiences. Clinical scheduling has extended beyond "banker's hours" to weekends and a variety of other shifts. Program delivery models have also been adjusted to allow for clinical placements during summer months, when units are more readily available.

Entry-to-Practice Requirements

The professional regulatory college is mandated by the government to set minimum entry-to-practice requirements in order to promote public safety and professional accountability. Usually, professional groups tell the regulatory college what these requirements should be. In most Canadian jurisdictions, entry-to-practice requirements for practical nursing include the following:

- Graduation from an approved postsecondary program for practical nursing, with the appropriate number of hours of theory and practice and with the appropriate courses taken
- A clear result of a criminal record check
- A sound knowledge base in all aspects of the nursing process (assessment, planning, implementing, and evaluating nursing care) for patients throughout the lifespan
- Ability to function independently and to function collaboratively with other health care providers, especially registered nurses, when caring for patients in more acute, unpredictable, or unstable conditions
- Ability to work in a variety of settings with individuals, families, groups, and in some cases communities
- Ability to apply ethical practice standards

- Ability to collaborate and communicate with others, including the patient and other health care personnel (including health teaching)
- Ability to be accountable for own actions and to work within the scope of practice
- Ability to be a lifelong learner
- Ability to cope effectively with change

It is important to note that these entry-to-practice requirements reflect minimal standards for safe, ethical, and competent practice (although that minimum appears to be increasing). These standards may also vary among jurisdictions.

Trend to More Education. For some time, the entry-to-practice requirements have increased (this phenomenon is also called *creeping credentialism*). A number of factors are thought to be responsible for this trend, including new and rapid developments in technology, increased public expectations, professional competitiveness and turf protection, increased postsecondary education trends, and expanded markets.

These increases in entry-to-practice requirements have both positive and negative aspects for the individual professional, the professions, the workplace, the government, and society in general. The positive effects may include increases in employment opportunities, national and international mobility, and the quality of service to the public and enhancement of research potential and development. The negative effects may include increases in educational costs for the individual and society, delay of the professional's entry into the job market, problems in workplace collective agreements, exacerbation of job shortages, and creation of economic burdens for employers because people with higher credentials tend to expect higher wages.

Continuing Education Issues

Laddering. Should health care aides be given the opportunity to become practical nurses? Should practical nurses be given the opportunity to become degree nurses? The concept of **educational laddering**, or *bridging*, recognizes prior learning and acknowledges that knowledge and expertise are acquired in various ways. It provides a means by which individuals can progress in their careers without being forbidden reasonable access to other levels or categories. Institutions across Canada are beginning to offer academic pathways that bridge health care aide and practical nursing programs, as well as practical nursing and registered nursing programs. The key phrase is "reasonable access." Because registered nurses and practical nurses aspire to different levels of practice, the applicant's previous experience must be carefully considered in order to protect the discipline of nursing.

Postgraduate Certification. Practical nurses can further their education and their contribution to the profession by specializing in specific fields.

Practical nurses have plentiful opportunities to obtain certification in specialty areas after graduation from a basic program. These certificates may be offered to practical nurses or to both registered and practical nurses. Examples of specialty areas are certification in operating room technique and management, foot care, gerontology and geriatric nursing, dialysis, women's health, specialized mental health, and occupational nursing.

The Role of the Practical Nurse

Most jurisdictions recognize that practical nursing is a separate category within the wider field of professional nursing. Most

jurisdictions also recognize that practical nurses and registered nurses learn about the same body of nursing knowledge. RNs study this content in more detail and over a longer period of time, while practical nurses study it for a shorter period, resulting in more focused knowledge.

Many practical nurses are employed in chronic care settings and in the fields of gerontology and geriatrics. Increasingly, however, health care agencies and institutions are hiring practical nurses in acute care and nontraditional settings where they may work independently or collaboratively with RNs. Consequently, practical nurse programs are teaching students to provide care for stable and acute care patients and are providing training for skills needed in acute care settings (e.g. intravenous therapy, oxygen therapy).

Table A-2 lists the percentages of practical nurses in Canada employed in different areas of responsibility in 2009.

Many practical nurses are eager to assume new roles and responsibilities in acute care settings, and they are legally entitled to do so. However, they may have difficulty obtaining employment and may be underutilized in these settings because many barriers arise from institutional culture, personal prejudices, and past practices.

As registered nurses continue to exert a large amount of control within the nursing profession, practical nurses may be restricted entry into certain aspects of the nursing niche. Most nursing managers are registered nurses with baccalaureate degrees or postgraduate degrees. They sometimes resist

allowing practical nurses into certain clinical areas for a combination of reasons: lack of understanding regarding the latest changes in practical nursing and scope of practice, belief that patients' acuity is too extreme for practical nurses, and fear of litigation, bureaucratic pressures, or union pressures to maintain registered nurses' positions. Practical nurses themselves may encounter difficulties because of personal fears associated with role change. As staffing proportions change, it is imperative that institutions establish clear mechanisms and policies that support effective utilization of both registered nurses and practical nurses in providing patient care.

Workplace Issues

The nursing profession currently has a high rate of **attrition** and frequent occurrences of stress and burnout in the workplace. Many factors create this climate of unease in the workplace:

- The pay is relatively poor for the work provided.
- Nurses face heavy workloads, and staffing patterns are complicated.
- Rates of overtime and sick time are high among nurses.
- Nurses face situations of ethical distress (Canadian Nurses Association, 2003).
- It is common for practical nurses to be working for several employers.
- Patients are entering hospitals with a higher level of acuity.
- Care requirements are becoming more complex.
- Health care delivery is continually shifting to meet patient needs (e.g., the shift to community and long-term care).
- Institutional support for nursing activities is either actually lacking or perceived to be lacking. Many practical nurses feel discouraged when the nursing system fails to recognize or fully use their abilities.
- Bed closures, downsizing, and use of unregulated care providers are increasing.

Workforce Issues

The number of practical nurses is increasing slowly, but an actual shortage is forthcoming as nurses reach retirement age, are downsized, are replaced by other personnel, or leave the nursing profession. Government and nursing bodies alike have identified the critical need for action to address the predicted nursing shortage through recruitment and retention strategies.

The nursing workforce is aging, and high retirement rates are pending. In 2009, the average age of Canadian LPNs was 43.4 years, with the proportion of LPNs in the 50 to 54 age group being the highest in most jurisdictions (CIHI, 2010, p. 76). The average age of graduating practical nurses between 2005 and 2009 was 30.9 years (CIHI, 2010, p. 74). These trends will influence future eligible years of service and will have a significant impact on practice settings in the future. The percentage of internationally educated licensed practical nurses has not significantly changed between 2005 and 2009, remaining at approximately 2%. The majority of these nurses are being educated in the Philippines and United Kingdom (CIHI, 2010, p. xii). Internationally educated nurses must meet regulatory requirements in Canada, which include writing registration examinations and meeting standards of academic preparation. Numerous bridge training programs are available to help qualified immigrants meet these requirements (Government of Ontario [Immigration], 2009).

TABLE A-2
Number and Percentage Distribution
of LPNs Employed in Practical Nursing
by Area of Responsibility, 2009

	Count	Percentage
Total direct care	74,805	98.1%
Geriatric/Long-Term Care	33,087	43.4%
Medical/Surgical	13,860	18.2%
Nursing in Several Clinical Areas	5090	6.7%
Psychiatric/Mental Health	3674	4.8%

Employment Trends

Practical nursing is one of the largest regulated health care professions in Canada, second only to registered nursing. In 2009, practical nurses represented 22.1% of the total regulated nursing workforce in Canada. CIHI estimated that in 2009, approximately 76,944 practical nurses were employed in Canada. This represents an increase of 18.5% since 2005 (CIHI, 2010, p. xii).

Table A-3 summarizes the number of practical nurses in the workforce for each province and territory from 2005 to 2009.

Employment Status of Practical Nurses. The proportion of full-time positions in practical nursing varies throughout Canada. In 2009, more than half (50.2%) of practical nurses in Canada worked full time; the remainder worked in part-time (33.7%) and casual (16.1%) positions (CIHI, 2010, Table 27, p. 65). The proportion of full- and part-time nurses in the workforce varied among jurisdictions. The highest percentage of full-time practical nurses was in the Northwest Territories, where 86.2% of all practical nurses were employed full-time in 2009. At the same time, Manitoba, in contrast, had the highest percentage of part-time practical nurses (54.7%) (CIHI, 2010, Table 27, p. 65). In 2009, 17.5% of practical nurses worked for several employers, which reveals an interesting trend (CIHI, 2010, Table 28, p. 66).

Workplace Settings. The proportion of practical nurses working in different settings currently varies across Canada. The public may think that practical nurses work exclusively in long-term care settings. This was indeed a key area of employment for about 43.4% of practical nurses in 2009. Only about 6% worked in the community, and approximately 6% worked in other areas (CIHI, 2010, p. 71). According to the CIHI (2010, p. 71), "other" places of employment include business, industry, occupational health care offices, private nursing agencies, private duty, physicians' offices, family practice units, self-employment, schools and other educational

institutions, government, and volunteer associations. It should be noted that practical nurses are also being employed as administrators, educators, and researchers (CIHI, 2010, p. 71).

These trends in workplace settings raise some concerns. If patients requiring nursing care are increasingly found in the community and not in institutions such as hospitals and nursing homes, then why are the numbers of practical nurses in the community or "other" settings so low? Perhaps these statistics reflect reluctance on the part of other health care workers to permit practical nurses to function at the full scope of practice for which they are prepared.

Standards and Scope of Practice

Standards of Practice

As a regulated profession, practical nursing is responsible for establishing its own **standards of practice**. The professional regulatory body for practical nurses in each jurisdiction (e.g., the provincial college of practical nurses) has the authority to set standards of practice for its members. It also has the authority to ensure that members meet these standards.

Standards of practice are written statements that detail the level of performance expected of nurses in a particular jurisdiction. They provide general guidelines about several aspects of professional practice and performance. The practice of any nurse can be continually measured against these standards. They also demonstrate to the public that the profession of practical nursing is dedicated to protecting public safety and providing high-quality care.

Although they differ in details, most standards of practice for practical nurses in Canada offer performance guidelines for the following areas (among others): the nursing process (i.e., assessment, participation in nursing diagnoses, planning, implementation, evaluation), ethics, education, leadership, research, and collaboration with other professionals.

Each individual nurse and the regulatory body are responsible for standards: the nurse for knowing and using them, and the regulatory body for publishing and enforcing them. In addition, the professional association and employers must support these standards in practice and in theory. Finally, members of the public are responsible for being good consumers of the professional health care they receive.

Ethics in Nursing. *Ethics* refers to the moral principles or values that **guide people** when they decide what is right and what is **wrong**. *Ethics* influence behaviour and relationships with other people. Providing ethical nursing care means that the nurse forms a dynamic, caring, helping relationship with the patient in order to help the patient achieve and maintain optimal health.

Regulatory bodies for practical nursing are responsible for establishing and promoting codes of ethics. These codes of ethics guide practical nurses in ethical decision making. They also uphold ethical standards for practical nurses. The following values are promoted in most codes of ethics for practical nurses:

- Being accountable for one's actions
- Upholding the patient's rights to privacy and confidentiality
- Providing care that maintains the patient's dignity
- Demonstrating respect for the patient at all times
- Promoting integrity by providing safe, competent, and ethical nursing care
- Evaluating one's work and maintaining competency

Continuing Education and Expanded Competencies. The practical nurse is expected to continue professional growth and acquire a range of knowledge, skills, and judgement beyond that of the minimal entry-to-practice standards. Many educational opportunities are available to the nurse from postsecondary institutions, professional organizations, employers, and charitable agencies (e.g., the Canadian Diabetic Association). Increasingly, nurses are encouraged to attend educational events offered by other health care providers, such as respiratory therapists, pharmacists, physiotherapists, and gerontologists. This cross-professional education is also immensely valuable in encouraging greater understanding and collaboration among members of the health care team.

Inevitably, nurses in various areas develop different competencies. This presents individual and workplace challenges. As individual competencies are enhanced and scopes of practice are expanded, nurses and employers must continuously seek clarification of their roles. Nurses are accountable for their actions at all times. The employer needs to remain fully aware of the new competencies of nurses, both at entry level and beyond. Employers must also develop clear policies to address the expanded practices of all nursing staff.

Challenges to Working to Full Scope of Practice. Perhaps the best way to maintain competency is to continually use skills and training. Unfortunately, some employers do not allow practical nurses to work to their full scope of practice. For both personal and political reasons, the potential of practical nurses is often not recognized by the health care system. This results in a mismatch between the “scope of employment” and the “scope of practice” that practical nurses are prepared for.

In response to the changing health care system—including employer demand, patient acuity levels, nursing shortages, and professional organizational efforts—many areas do make efforts to allow practical nurses to apply their full scope of practice. This shifts practical nurses from a task orientation to a competency base and, in the process, improves patient care and professional job satisfaction. Optimizing and clearly defining roles for both categories of nurses can also lead to more cost-effective nursing care.

Collaboration

The practical nurse is a team member and thus should always work in a collaborative manner with other health care personnel. Collaboration includes communicating with the patient, the family, and other health care workers to define, implement, and evaluate the plan of care. Collaboration with the patient and family includes focusing on real and perceived needs and wishes and how they intersect with medical and nursing plans. Good working relationships and collaboration between practical nurses and registered nurses in the team are essential in the delivery of quality patient care. The practical nurse also makes suggestions and referrals to individual members of the health care team and in team meetings in which patient care and concerns are discussed. Full understanding of all roles and clear and appropriate communication are integral to effective collaboration within a team.

Scope of Practice

Scope of practice refers to the legal limits of a professional role. Four categories of health care providers give nursing care: unregulated care providers (e.g., nurse’s aides, personal support workers), practical nurses, registered nurses, and

TABLE A-4
Scope of Practice Requirements
for Practical and Registered Nurses
in New Brunswick

	Practical Nurse	Registered Nurse
Entry-level education	Completion of a recognized certification program and successful completion of the Canadian Practical Nurse Registration Examination	Completion of a recognized baccalaureate program and successful completion of the Canadian Registered Nurse Examination
Patient	Educated to provide care to individuals, families, and groups throughout their lifespan, across the continuum of health	Educated to provide care to individuals, families, groups, populations, and communities throughout their lifespan, across the continuum of health
Context of practice	Works as a team member in all settings	Works as an independent practitioner or team member in all settings
Implementation	Coordinates care of less acute, less complex, less variable patients with more predictable outcomes Provides elements of care for highly complex patients in close consultation with the RN coordinating that patient’s care	Coordinates the care of patients regardless of acuity, complexity, variability, and predictability Directs plans of care for highly complex patients

Adapted from Nurses Association of New Brunswick and Association of New Brunswick Licensed Practical Nurses. (2009). *Working together: A framework for the registered nurse and licensed practical nurse* (pp. 10, 11). Retrieved from <http://www.anblpn.ca/English/home/dynamic.cfm?id=92>.

nurse practitioners. Each category of health care provider has its own scope of practice. These scopes of practice are different because each category of health care provider has different education, legal authority, and performance requirements.

In Table A-4, the scopes of practice for practical and registered nurses in New Brunswick are compared. The specific scope of practice may differ among jurisdictions; however, it is common to find that as the complexity, acuity, or variability of a patient increases, practical nurses require more collaboration and support from RNs. This support may initially involve consultation with the RN and may lead to sharing the patient assignment with the RN or the RN taking responsibility for the patient (Licensed Practical Nurses Association of Prince Edward Island, 2011). It may be within a practical nurse’s scope of practice to care for a stable postoperative patient;

Figure A-1 Balancing patient needs with RN and LPN scope of practice. **Source:** Licensed Practical Nurses Association of Prince Edward Island. (2011). *Exemplary care: Registered nurses and licensed practical nurses working together* (p. 13). Retrieved from http://www.lpna.ca/practice_policy.php.

however, if the patient's vital signs become unstable and urine output decreases below normal limits, the condition of the patient may require care that exceeds that scope of practice. In this case, when the practical nurse recognizes that the patient's condition has become more complex and unpredictable, she or he would consult with the RN and may determine that the patient is experiencing signs of shock and requires physician attention. It is essential that practical nurses and RNs are aware of each other's scopes of practice as this will enhance their ability to work collaboratively to determine and deliver the most appropriate plan of care.

Figure A-1 illustrates how a patient's health needs may call for consideration of the scope of practice of the LPN and RN and may result in a shift in the manner that care is provided.

Boundaries between scopes of practice vary. Between registered and practical nurses, the scopes of practice are much less definitive, and the boundaries are sometimes blurred because both levels of nurses share a base knowledge and practise and develop new competencies during clinical practice. However, the boundaries between practical nurses and unregulated care providers are more definite because little of the basic knowledge or competencies are shared between the two roles.

Leadership: Supervising and Delegating. The practical nurse is often in a position to supervise or to delegate, as well as to be the recipient of **supervision** and **delegation**. In order to supervise and delegate, the practical nurse must have sufficient knowledge, skill, attitude, and judgement. Both supervision and delegation, although different skills, serve to protect the public and the profession by ensuring that a task is performed safely and competently. The same principles of supervision and delegation are applicable to all levels of nurses.

Supervision. Supervision is usually required by individuals who are new to a skill or role, such as students of a profession, new members of a profession, and professionals or nonprofessionals (such as family members or unregulated care providers). The person who is supervising usually has experience in that knowledge and skill, and he or she may or may not be a member of the same profession or occupational group.

Supervision is an intervention and usually an ongoing relationship. The purposes of supervision are (1) to enhance

competent functioning of an inexperienced person and (2) to protect the public and the professional practice. Because supervision requires continual observation, monitoring, and evaluation, the supervisor must have a positive, collaborative relationship with the person being supervised. Both parties in the relationship must understand the roles each must play. The ongoing nature of most supervision allows the relationship to grow and develop. People should be supervised until they can safely perform the task alone. Supervision may occur in many forms, such as a one-on-one observation, an interview with the patient who has received care, or an analysis of the written report of a task. The supervisor provides evaluative information about the task performed as soon as is feasible.

If supervision of a skill occurs in a more isolated instance, the development of a relationship and the analysis of progress are more difficult.

Delegation. In delegation, authority to perform a restricted task or function is transferred to another person or group. The nurse must make this decision carefully. Professional standards are quite clear in this matter. Before delegating a task to another, the nurse must ensure that the person has the required knowledge, skill, and judgement to perform that function. The nurse must consider numerous other factors before a function is delegated to someone else: the associated risks and benefits for the patient, the need for another person to perform the task, the ability of the person to maintain **competence** in the procedure over time, and the ability to provide adequate supervision once the skill has been learned. The Commonwealth of Massachusetts (2011) identifies the "five rights of delegation" for nurses: (1) the right task, (2) the right circumstances, (3) the right person, (4) the right direction or communication, and (5) the right supervision and evaluation. These rights are applicable to nurses working at all levels.

In addition, the nurse must know institutional policies and procedures about delegation and whether the particular function may be legally delegated. This is particularly crucial because of the increasing numbers of unregulated care providers with varied skill sets and functions within the health care system. Responsibility does not stop once a task is delegated to another person. The delegating nurse retains ultimate responsibility for the correct completion of the task. The College of Nurses of Ontario (2009b) developed a useful decision tree to help the nurse decide whether a function can be delegated to another person (Figure A-2).

Clinical Skills. Although graduates of practical nursing programs are prepared to perform skills that are considered entry-to-practice competencies, many factors dictate their ability to do so in the workplace. Medication administration is one of the specific knowledge-based clinical skills that is within the scope of practical nursing in some jurisdictions but may not be in others. Even if it is part of the scope of practice, institutions may be reluctant to allow practical nurses to use this skill. In some areas, boundary issues arise with accompanying confusion about who may administer what medications, to whom, and when. In some jurisdictions, practical nurses may administer injections, monitor intravenous therapy, and administer intravenous medications; in other jurisdictions, they may not. Practice related to clinical skills varies tremendously across the country, between institutions in a region, and even within an institution itself.

Additional Clinical Skills. In most cases, practical nurses can and do acquire other clinical skills beyond those needed for entry to practice. The restrictions on these skills are the

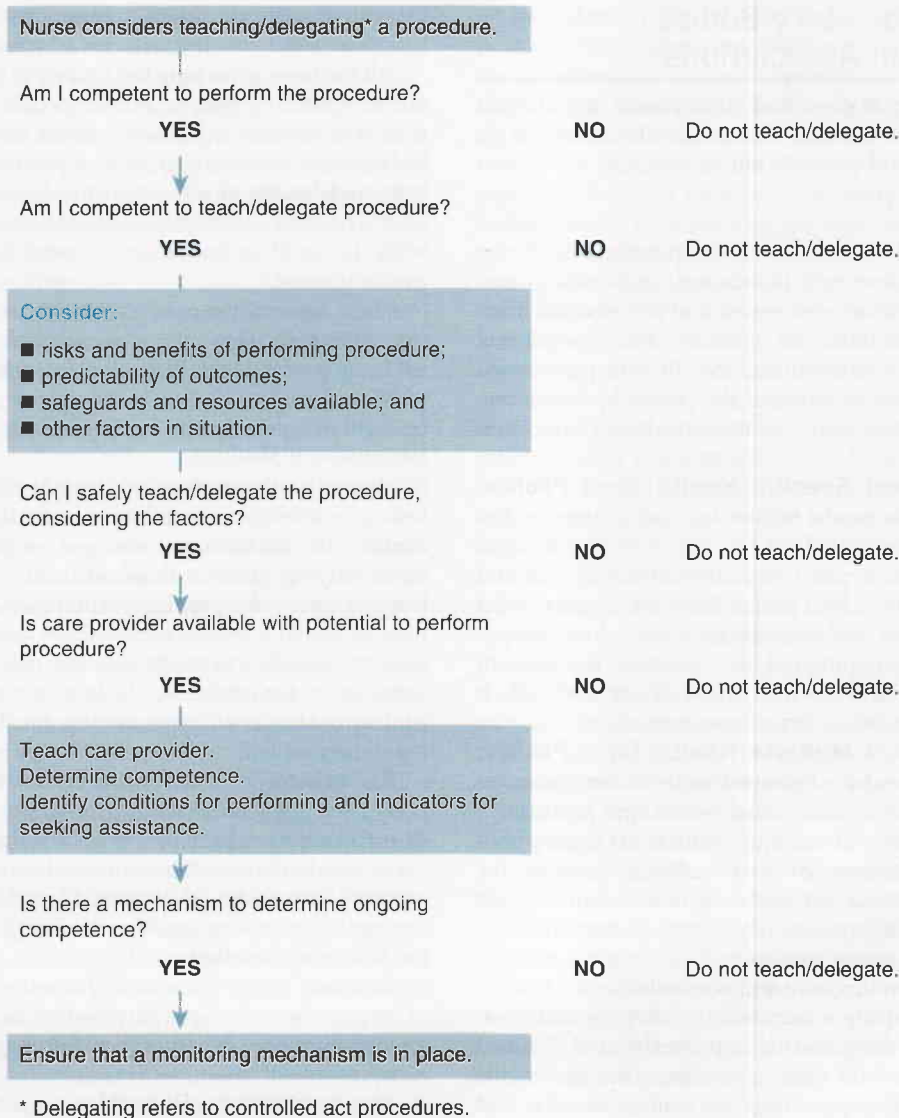

Figure A-2 Decision tree for teaching or delegating performance of a procedure. **Source:** College of Nurses of Ontario. (2009b). *Working with unregulated care providers* (p. 16). Retrieved from http://www.cno.org/Global/docs/prac/41014_workingucp.pdf.

same as those for the registered nurse; the practical nurse must usually take a specific post-basic course to acquire the needed knowledge and skill base and must usually be employed in an area allowing frequent enough application of these skills to maintain continued competency levels. For example, courses are available to learn about various types of dialysis, but entry into these courses is usually confined to those employed or soon to be employed in this area, where they will require the skill and will be able to use it often enough to maintain competency.

Whether an added skill may be practised by a practical nurse is sometimes restricted by legislation or local institutional or regional health care policy, or both. Theoretically, any health care skill that a family member or layperson can be taught should be learned by a nurse, the parameters being the same: a proper knowledge base and demonstrated initial and continued competency and judgement in application of the skill. However, practical nurses need to be aware of the

possible unique legal restrictions on their roles. Whether sensible or not, these legal restrictions do not apply in the same way to family members.

Because the situations necessitating nursing are increasingly complex, variation has arisen in the functions that can be assigned to practical nurses. Some of the more common added competencies for practical nurses in many jurisdictions are operating room techniques, special foot care, orthopedic care, gerontology, community care, and specialized mental health care.

The only commonality appears to be continued rapid change. The nurse must be careful never to assume that standards and scopes of practice are the same within or between institutions, between jurisdictions, or over time. One way to keep pace with change is to keep in close contact with a variety of sources: the professional association, the regulatory body, agency policies, and the ever-expanding body of health care knowledge.

Legislation, Regulatory Bodies, and Professional Associations

Legislation, regulatory bodies, and professional associations govern the practice of nursing. These have been created to protect public safety and promote ethical practice.

Legislation

In most provinces and territories, nursing practice has similar legal regulatory requirements (education, registration, and complaints and disciplinary processes) and professional standards (scope and standards of practice, and competency issues). Laws that govern regulated health care professions serve to protect the best interests of the public by regulating health care practitioners and determining how, what, and where they practise.

Acts That Govern Specific Health Care Professions. In most provinces and territories, each profession has its own governing law, called an *act*. For example, medical doctors, registered nurses, practical nurses, chiropractors, and so forth each are governed by a professional act. These acts list specific tasks that those professionals are allowed to perform because they have the required skills. However, the skills of one profession often overlap with those of another, which causes confusion for public and professionals alike.

Acts That Govern Multiple Health Care Professions. Some provinces have removed or are in the process of removing separate acts for individual health care professions and are replacing them with a single, generic act that applies to all health care professions. In Ontario, this act is called the *Regulated Health Professions Act*, and in British Columbia, it is called the *Health Professions Act*. This trend is occurring for several reasons:

- The public is demanding safe and accountable practice.
- New technology, which is increasingly complex and invasive, is potentially dangerous if improperly used. Trained professionals must, with great care, administer treatments such as radiation therapy, drugs for cancer, surgery, and injections.
- People requiring health care have increasingly complex physical, emotional, and social needs.
- As many professions expand their scope of practice and acquire new knowledge and skill sets, significant overlap in knowledge and skills occurs between various groups. These general health care acts are an attempt to apply a regulatory structure common to all groups.
- Health care professionals are more mobile today (i.e., they move between jurisdictions) and may have wide variations in knowledge and competence.
- The number and variety of health care professions have increased.
- These generic health care acts list (1) professions that are regulated by the law and (2) activities that only members of certain professions are authorized to perform. These activities refer to restricted actions that would be considered to be potentially harmful if performed by anyone other than a qualified professional. They are identified as **controlled acts** (in Ontario) and **reserved acts** (in British Columbia).

Different health care professions are legally permitted to perform certain restricted activities. For instance, diagnosing a disease is a controlled act that is usually restricted to the medical profession, while administering a substance by injection is an act that can usually be performed by nurses. In

Ontario, the *Regulated Health Professions Act* lists 13 controlled acts, 3 of which can be performed by nurses (CNO, 2009a).

All the laws governing the actions of health care professionals, whether they are profession-specific acts or generic health care acts, include statements about the type of educational background necessary to enter a professional school and the type and length of education the professional schools must offer. The laws also require the profession to set up a governing body to monitor and regulate professional practice in the public interest.

These laws may seem excessively cumbersome and confusing. However, they are a reasonable attempt to establish uniform professional competencies and thereby protect the public.

Regulatory Bodies

According to the professional and health care acts, each profession must have a regulatory body that governs it. As the health care environment changes, regulatory bodies adapt by modifying practice standards and guidelines accordingly. Depending on the province or territory, this regulatory body may be called a *college*, a *council*, an *association*, or a *board*. Its primary mandate is to protect the public by controlling the activities of the professionals. In order to practise or use their professional title, all professionals must be members of their regulatory body.

Functions of the Regulatory Body. Each regulatory body uses many methods to protect the public. It ensures that its members have been properly educated; meet the minimum entry standards; maintain continued competence; and have the required knowledge, skill, attitude, and judgement to practise the particular profession. Almost all regulatory bodies perform the following functions:

- Ensuring that professionals have the necessary credentials to practise in the specific province or territory
- Determining whether qualifying examinations are necessary
- Registering the professional as a member of the profession once all criteria for membership have been met
- Keeping a public register of the names, registration numbers, and business addresses of all members
- Defining scope of practice and competency standards, according to professional standards and the existing laws
- Ensuring that members renew or update registration and maintain competency criteria on a regular basis
- Receiving complaints from the public or other professionals about personal practices of members, investigating these complaints, and disciplining members as necessary
- Publishing disciplinary results regularly (i.e., name, registration number, offence, and disciplinary decision)
- Approving practical nursing programs in their jurisdiction

Because the names, registration numbers, and business addresses of registered health care providers are made public, some people have expressed concern that members' right to privacy is compromised. However, regulatory bodies and most provincial and territorial governments believe this information is necessary for public safety. Therefore, they consider that protecting the public safety supersedes the provider's right to privacy. In many areas, governments also permit the publication of disciplinary action against a health care provider, believing that doing so fulfills this mandate of serving the best interests of the public.

Protecting or Reserving Titles. Usually, regulatory bodies are also responsible for ensuring that the members' professional title (e.g., LPN, Dr.) is protected, or reserved. This means that only registered members are authorized to call themselves by the professional title. The protected title is usually related to the terms used in the jurisdiction, but protection is usually also extended to other, synonymous terms. For example, in Ontario, all the following related terms and abbreviations are protected: *nurse*, *registered practical nurse*, *RPN*, *LPN*, *PN*, and their variants.

The provincial or territorial college of licensed practical nurses is the provincial regulatory body responsible for superintending the profession of licensed practical nursing in the public interest. As such, the college sets the requirements for the privilege of using the professional titles related to licensed practical nurses. The professional title assures the public and other care providers that the individual has been evaluated and found capable of practising within the established standards.

In all provinces and territories (except Ontario), the official designation of the practical nurse is *licensed practical nurse* (LPN). In Ontario, the official designation is *registered practical nurse* (RPN).

Obtaining Criminal Record Checks. Because professionals have positions of power, concerns have inevitably arisen that they could take advantage of vulnerable people, especially young children and older adults. In response, provinces and territories require individuals registering with a regulatory body to undergo a criminal record check.

Self-Regulation. To what extent should governments be involved in the regulation of a health care profession? Surely professionals are capable of regulating themselves and do not require paternalistic interference from government bureaucrats. The public good must be balanced with individuality, as must government laws with professional input. Professional self-regulation in nursing means that each nurse is expected to assume personal responsibility for maintaining competence and personal, physical, social, and emotional fitness to practise. Self-regulation also means that nurses establish standards of practice and an ethical framework for the nursing profession as a whole.

Self-regulation is a privilege that is entrusted to a regulating college in order to serve and protect the public interest:

The college establishes requirements to enter the profession and assures the quality of the practice of LPNs through the development and enforcement of standards of practice and continuing competence programs. (College of Licensed Practical Nurses of Manitoba, 2011)

The Registration Process for the Practical Nurse (Credentialling). In all territories and provinces of Canada, registration with the local regulatory body must proceed through a specific process. The regulatory body (also called a *registering body*) in each jurisdiction determines whether the applicant has sufficient educational background and competency for registration in the particular area. To be registered as practical nurses, applicants must prove that their education meets requirements for theoretical and clinical hours in specified topics and clinical areas. They also must provide evidence of competent practice by passing a licensing examination, providing evidence of recent competent work in the practical nursing field, or both. As already noted, in many jurisdictions, applicants must also pass a criminal record check before registering to practise.

Registering Locally. Successful graduates of a practical nursing school submit their names to the local licensing authority for permission to write the national certification examination, the Canadian Practical Nursing Registration Examination. As a general rule, students must write the certifying examination in the province or territory in which they received their education because their local registration body must recommend them to write the examination. The students are notified of where and when examinations will be written. After the examination is written, the student is notified of the results by mail. Usually, the school receives a summary of the passing and failing marks in that class and information about their success in relation to other schools in the jurisdiction and country. Privacy of examination marks is an issue in many areas. In Ontario, for instance, students must sign a waiver allowing their examination results to be included in the information sent to their educational institution. When the examination results are sent to the school, the student names are obscured.

After passing the licensing examination and (if required) completing a criminal record check, the new graduate then applies to the regulatory body to be registered as a practical nurse.

Registering in Another Province or Territory. Just as they would in their own jurisdictions, applicants wanting to register in a province or territory in which they have not been educated must formally apply for registration. This generally means the applicants must submit official transcripts from their school, indicating both hours and topics of theory and practice they completed in the basic program. They must show competent practice by submitting a record of success in the national certification examination or its equivalent from another country. If they are not recent graduates, they must also provide evidence of a sufficient amount of recent (within the previous three to five years) appropriate work in practical nursing. If they have not already done so, they may have to complete a criminal record check. If the certification examination, educational background, or recent nursing experience is not accepted by the regulatory body, then the applicant may be required to write the Canadian examination and take theoretical or clinical nursing courses to upgrade to Canadian standards.

Registering in Other Countries. The registration process for the United States and the United Kingdom is very similar to the Canadian process. The applicants must prove to the foreign regulatory body that (1) they have successfully completed a basic nursing education program that includes a specified number and type of theoretical and clinical hours, and (2) they are capable of competent nursing practice (i.e., they have successfully written the examination or have recent practical experience, or both). Countries vary in how they accept marks on Canadian certification examinations and hours in clinical and theoretical basic nursing programs. In the United States, nurses are certified in the specific state or territory; in the United Kingdom, nurses are certified nationally.

Practical nurses planning to relocate to another jurisdiction (country, state, or province) should contact the new registering or licensing body well in advance because this body may have different requirements for professional practice. The procedure for attaining registration in a new jurisdiction can take up to three months in the absence of complications or deficiencies, but it can take much longer if problems exist.

Professional Associations

In Prince Edward Island and Ontario, the professional association is separate from the regulatory body (e.g., the College of Nurses of Ontario is the regulatory body, and the Registered Practical Nurses Association of Ontario is the professional association). However, in all other provinces and territories, they are the same body. The purpose of most professional associations is to advocate for and promote the particular profession they serve. The objectives of the Registered Practical Nurses Association of Ontario (2011b) include the following:

- To advocate for RPNs in diverse settings, resulting in optimum patient health services through policy, legislation and regulation
- To advocate for quality, respectful working environments for RPNs
- To enhance the professional competencies of RPNs by ensuring the research, development, and delivery of quality educational programs
- To promote the benefits of membership to RPNs in order to ensure a strong and unified professional voice
- To promote a closer working relationship with other health and related organizations
- The fundamental differences between a regulatory body and a professional association have been highlighted. Protection of the public is the distinct mandate of the regulatory body, whereas promoting professional development is the mandate of the professional association. Many nurse leaders and politicians believe that regulatory bodies and professional associations should not be combined because doing so may lead to public confusion and conflicts of interest. In the interests of both professional issues and public accountability, the professional association and regulatory body must remain in continuous, effective communication.

Practical nurses in provinces and territories that do not have a professional association separate from the regulatory body can access the Canadian Practical Nurses Association (CPNA) for professional advocacy and promotion issues. Unlike membership in the regulatory body, membership in the professional association is usually voluntary.

The Canadian Association of Practical Nurse Educators, an affinity group of the nationwide Association of Canadian Community Colleges, offers educational and networking opportunities and holds yearly conferences for educators throughout Canada.

Benefits of Membership in the Professional Association. Members of professional associations enjoy the following benefits:

- Receiving emotional support from other professionals by sharing thoughts, feelings, and ideas
- Enhancing a personal and collective knowledge base, thus contributing to individual and group growth
- Being part of a strong force for change (groups often lobby for change more effectively than do individuals)
- Achieving some economic advantages (e.g., better insurance rates through a group plan)
- Having opportunities to network

In summary, nursing is a complex profession that exists in a challenging environment under constant legal and professional changes. No nurse works alone; he or she is always in an environment with the public and other health care providers. Each nurse must understand how legislation, regulatory

bodies, and professional associations work together to inform safe and competent practice.

The Future of Practical Nursing in Canada

It is not possible to know the future of practical nursing definitively, but it is possible to make reasonable predictions on the basis of current and projected trends. The health care system in Canada is continually changing, and these changes have an effect on practical nursing. Both Abbot (1988) and Wilson (1992) believed that organisms and professions that do not respond to change lose their niche positions and either fade to unimportant entities controlled by others or die out completely. According to Wilson, "Homogeneity means vulnerability" (p. 301). In order to cope effectively, nurses must be **proactive** and view change as a challenge and an opportunity rather than a threat. By doing so, nursing will maintain or advance its niche position in health care.

General Health Care Trends

A number of current and projected changes can potentially affect practical nursing. The following issues each have an impact on the delivery of health care services in Canada:

- Rising costs of health care; the individual consumer will need to pay more
- Increased privatization of health care with less government funding
- Increased use of technology, including robotics for treatment and computer technology for communications, documentation, and teaching
- Expanded public access to information
- Increased population diversity
- Stronger public demands for a voice in health care and competent health care services
- Increased medical legal litigation
- Higher percentage of older adults in the population
- Trends toward postacute care, rehabilitation, palliative care, long-term care, and chronic care in the home rather than in hospitals or other institutions
- Increased acuity of admitted patients
- Proliferating interprofessional models for health care

In the Canadian Nurses Association's report *Toward 2020: Visions for Nursing*, Villeneuve and MacDonald (2006) identified trends that will affect Canadian nurses of the future. They predicted that by 2020, chronic diseases and virulent infectious diseases would increase in number, health care would focus on wellness promotion, more health care would take place in homes and communities, interdisciplinary care would be the norm, technology would continue playing a major role in health care, foreign-trained nurses would be integrated into the Canadian workforce, and nursing credentials from different provinces and territories would be accepted across Canada.

Specific Health Care Issues in Canada

The Romanow report (Government of Canada, 2002) offered several suggestions about the unique needs of Canadians that affect practical nursing:

- Government should increase strategies that promote physical activity and reduce obesity.
- Efforts to reduce smoking should be expanded.

- Immunization programs should be given closer attention, especially in response to new infectious diseases and increased population mobility between countries.
- Services to new Canadians, visible minorities, people with disabilities, Aboriginal people, and rural and isolated populations should be given more attention and funding.
- Home care is one of the fastest-growing sectors of the health care system; investing more in home care will improve services and quality of life for home care patients and will also save the system money by keeping people out of hospitals and long-term care facilities.
- Better services should be provided in mental health care, postacute care, rehabilitation, and palliative care.
- A national approach to human resources planning for health care should be developed so that one province does not “poach” scarce health care providers from other provinces.

Implications for Practical Nursing

Continuous rapid change requires professionals to respond appropriately in order to cope effectively. Practical nurses need to be lifelong learners and develop increasingly broad-based competencies to adapt to changing occupational demands. This is not the time to focus solely on one narrow skill set or to cling stubbornly only to the knowledge base acquired in undergraduate school.

Modern technological treatment is increasingly expensive and time intensive. Practical nurses have the knowledge, abilities, attitudes, and skills to contribute significantly to newly evolving primary health care models. Practical nurses of the future will likely need to have increased knowledge of **epidemiology** and to play a greater role in illness prevention, health promotion, and health teaching for patients throughout the lifespan. For instance, nurses will likely be required to provide information to reduce infectious and chronic lifestyle-related diseases such as cancer, diabetes, obesity, and heart-lung disorders. Health teaching for individuals and groups in the areas of diet, exercise, and reducing high-risk habits such as smoking will become increasingly important. Practical nurses will continue to need to focus on patients and empower them to be active participants in their own health care. Because health care problems are often too complex to be addressed by any one person, practical nurses will need to focus more on working collaboratively in teams and networks of health care providers. The trend toward interdisciplinary health care models will require nurses to be increasingly aware of scope of practice and of changes in scope of practice among all workers. Because of this emphasis on collaborative teamwork, outcome-based care frameworks (in the text, called care maps or critical pathways) will probably be emphasized over more narrow frameworks unique to only one profession (such as the nursing care plan). Having all health care team members work from the same model would simplify care issues and reduce the chance of error.

As more health care services are offered by the private sector, nurses will likely encounter different and challenging ethical issues. Nurses will need to be more aware of conflicts of interest. They may find that their professional values clash with corporate interests. In this regard, professional colleagues and the professional association will become increasingly important sources of information and support. Practical nurses will have to consider strengthening their national association

and, in some provinces and territories, having more direct and local input in their provincial or territorial association.

The increased use of computers in health care is resulting in remarkable advances in health informatics systems. Computer use has become the norm rather than the exception in most health care institutions. Practical nurses will need to become skilled in the use of electronic medical health record systems, which can involve documentation and full access to current and past medical records, diagnostic test results, and digital radiographic images. New technologies are changing bedside care as nurses begin to use personal digital assistants (PDAs), mobile or cell phone pagers, computerized medication administration systems, online educational resources, and telemedicine systems. Computer literacy will be essential for practical nurses of the future. Nurses work with an increasingly diverse and multicultural population base. Practical nurses of the future will thus have to develop more knowledge and skill in applying concepts from the humanities and social sciences such as psychology, sociology, and anthropology.

Possible Evolution of the Practical Nurse Role

Changes in Educational Standards for Entry to Practice. In view of the likely expanding roles for the practical nurse, a high school diploma will continue to be the minimum requirement for entry into a practical nursing program. The applicant must have a firm grounding in communication skills (written and oral), as well as in advanced sciences to cope with the increased scientific base of nursing. Some knowledge of or fluency in a second language would be useful in this increasingly multicultural society.

Practical nurse education programs need to be at least two academic years in length and must occur in a postsecondary institution that meets general program standards for preparing professionals to meet entry-to-practice requirements. These programs must be academically sound and include components of pure science, social science, and humanities. The curricula must also incorporate interprofessional education. Should the practical nurse decide to continue with studies in registered nursing, the practical nursing program should be accepted in whole or in part toward a university baccalaureate program. As noted earlier in this chapter, “laddering” into registered nursing is not the only option for practical nurses to enhance their professional careers. Many opportunities exist for nurses to gain expertise in specific health care areas while retaining a practical nursing identity. Practical nurses with advanced skill sets become valuable members of the health care team.

Should a university degree in practical nursing be available? Some places in the United States offer degrees in practical nursing, but this raises some questions. If university degrees become common, what would be the difference between practical nursing and registered nursing? Would the levels of nurses and their currently separate scopes of practices become even more blurred, or would they merge? Does the public need two very similar practitioners with the same education?

If practical nurses required degrees, this would mean registered nurses would be required to have master’s degrees. A master’s degree might even become a requirement for entry to practice for the registered nurse. This is already happening in the United States and much of Canada, where a master’s degree in nursing is required for almost all entry-level teaching or administrative positions and most nurse

practitioner (registered nursing extended class) positions. This scenario may appeal to health care agencies because they could employ more practical nurses, presumably for less cost than the same number of registered nurses. However, if university degrees in practical nursing were required, professionals educated at this level would demand higher pay and the health care system would not be much further ahead economically.

Will practical nursing remain a recognized health care profession, or will it be swallowed up by professions on either side of it (the registered nurse with baccalaureate degrees on one side and the unregulated care providers on the other)? If practical nursing fails to maintain or expand the knowledge base, then unregulated care providers may begin to absorb nursing competencies into their own skill set.

Scope of Practice and New Competencies. The practical nursing profession faces an exciting future. The practical nursing scope of practice will continue to evolve in response to changes in the Canadian health care system. CNA's *Toward 2020* report (Villeneuve & MacDonald, 2006) proposed that the structure of the health care system and the delivery of nursing by regulated nursing professions will be very different in the future. They predicted that by 2020, registered nurses would undertake more of the primary care that is currently provided by general practitioners. If this becomes reality, how will it affect the role of practical nurses? The report also predicted that by 2020, the proportion of practical nurses would increase and that the majority of nurses would work in community settings and in multidisciplinary teams. It suggested that practical nurses would play a greater role in preoperative, preprocedure, and perioperative settings and would be primarily responsible for rehabilitation and long-term care, with the assistance of personal support workers. Acute care in 2020 was further envisioned as consisting of a combination of all categories of nurses (Villeneuve & MacDonald, 2006). Despite changes in roles, collaborative practice between RNs and practical nurses will continue to be an important component in health care delivery.

Practical nurses of the future will continue to acquire separate postgraduate competencies in specific areas through post-basic education and on-the-job training and experience. In the future, more of these competencies may involve community health care, consultations and advice by telephone ("tele-health"), disease prevention (epidemiology), rehabilitation, palliative care, special needs populations, and health teaching opportunities for groups and individuals. Practical nurses will also probably have many opportunities to work with multicultural groups, including new immigrants, Aboriginal and other indigenous people, and rural populations, and they will continue to work in long-term and chronic care settings.

If professionals in acute care increase their use of the critical pathway (care map) system, practical nurses could have expanded roles in areas such as intensive care units. They would be able to work with more unstable patients because the critical pathway system allows for more interdependence and collaboration, technological and personnel help, and distinct instructions for care and consultation. The registered nurse would continue with the role of case manager.

Currently, registered nursing requires a greater depth of knowledge and a broader practice base than does practical nursing, and it exerts great influence on scope of practice among all categories of nurses. Practical nursing associations of the future will persist in addressing strategies to challenge restrictions imposed by other nursing groups. As all categories

of nursing professions face the future, it is imperative that they engage in dialogue and planning to ensure that their future roles and scopes of practice most effectively serve all stakeholders in the Canadian health care system.

What Is the Final Answer?

What will happen to practical nursing in the future? No one knows for certain, but ecological and sociological studies of professions indicate that individuals and groups—both animal and human—grow, develop, change, flourish, fade out, and disappear. According to Wilson (1992), "Environment is the theatre and evolution is the play" (p. 80).

Practical nurses and registered nurses are likely to always maintain separate scopes of practice for survival reasons. But practical nursing can strengthen its position by developing more diverse and specialized competencies in this changing society. It must develop competencies that address the needs of the environment. It must change to meet health care demands. For nurses, health care—more specifically, nursing—is the theatre, and constant change is the play. If practical nurses wish to maintain their particular niche in the health care system, it is essential that they respond effectively in this environment of continued rapid change.

✦ KEY CONCEPTS

- Practical nursing is the second-largest group of regulated health care providers in Canada.
- After the Second World War, nursing registration laws were amended to create two levels of nursing practice.
- Practical nursing was recognized as a distinct profession that necessitates formal education in the 1970s.
- Education programs for practical nurses have become longer and more complex and have moved from hospital settings to postsecondary institutions.
- Ecology theory describes the need for a group to compete for niches and evolve to cope effectively with environmental changes.
- In most Canadian jurisdictions, practical nursing programs are diploma programs that run for two academic years and are offered at postsecondary institutions.
- The main difference between registered nurses and practical nurses is the scope of their knowledge base.
- Practical nurses have a strong foundation in clinical practice, decision making, and critical thinking.
- Practical nurses work in a range of settings, including direct care, administration, education and research.
- As a regulated profession, practical nursing is responsible for establishing its own standards of practice.
- Practical nurses are expected to continue professional growth and acquire a range of knowledge, skill, and judgment beyond that of minimal entry-to-practice standards.
- Delivery of cost-effective nursing care considers optimizing scope of practice and clearly defining roles for both categories of nurses.
- Self-regulation is a privilege that is entrusted to a regulating body in order to serve and protect the public interest.
- Continuous change in the health care system requires the practical nursing profession to adapt in regard to entry to practice and scope of practice.

✦ CRITICAL THINKING EXERCISES

1. According to the CNA's *Toward 2020* report, the delivery of nursing by regulated nursing professionals will be different in

- the future. If, by the year 2020, registered nurses begin to play a larger role in primary health care, how will that affect the future roles of practical nurses and personal support workers? How would you design the human resources structure of the Canadian health care system of the future?
- Noreen, the manager of a surgical unit, is reviewing her tight budget and staffing complement. One-quarter of her staff consists of practical nurses and the remainder consists of RNs. The responsibilities of the practical nurses have not changed on her unit for the last 10 years. Based on what you know about scope of practice and delegation, what suggestions would you have for Noreen? What resources would you suggest that she access?
 - A newly graduated practical nurse is caring for a patient after a total knee replacement. Eight hours after the patient's return to the unit, he begins to complain of shortness of breath and chest pain on inhalation. The nurse identifies that oxygen saturation levels are falling and air entry is decreased to the patient's left lower lobe. The nurse has never encountered this type of a situation before. Describe how the practical nurse and RN can partake in consultation and collaboration in this situation.
- ### ❖ REVIEW QUESTIONS
- In order to identify him/herself with the title of licensed practical nurse (LPN) or registered practical nurse (RPN), a nurse must
 - Have completed an accredited practical nursing program
 - Be registered with a provincial regulatory body
 - Pass the Canadian Practical Nursing Registration Examination
 - Have procured employment as a practical nurse
 - The scope of practice for practical nurses
 - Varies between jurisdictions across Canada
 - Is limited to caring for stable patients
 - Is mandated by federal legislation
 - Has remained unchanged over the last decade
 - According to ecological theory, surviving groups
 - Establish limited niches
 - Cope with environmental change
 - Remain homogeneous
 - Avoid hybridization
 - Which of the following depicts the concept of laddering in health care education?
 - An LPN advances herself by taking an IV course.
 - An LPN begins an RN program pathway that gives consideration to his previous education and experience.
 - An LPN who has taken business courses is promoted to the position of team leader.
 - An LPN obtains her certification as a wound care specialist.
 - In Canada, practical nursing was established in which decade as a distinct profession that required a formal education?
 - 1900s
 - 1930s
 - 1970s
 - 1990s
 - Which of the following health care providers is not licensed under law in Canada?
 - Personal support worker
 - Practical nurse
 - Registered nurse
 - Nurse practitioner
 - Workforce and employment trends for practical nurses in Canada reveal that
 - Practical nurses are the second-largest group of regulated health care providers in Canada
 - The vast majority of practical nurses are employed in part-time positions
 - Practical nurses work exclusively in long-term care settings
 - The number of practical nurses is not being affected by the nursing shortage
 - In most Canadian jurisdictions, practical nurses graduate from
 - Certificate programs
 - Two-year college diploma programs
 - Three-year degree programs
 - Direct practice hospital programs
 - The activities that practical nurses are educated and authorized to perform are outlined in
 - Entry-to-practice competencies
 - Their scope of practice
 - Terminal outcomes
 - National law
 - Which of the following are included in most codes of ethics for practical nurses?
 - Controlled acts
 - Upholding the patient's rights to privacy and confidentiality
 - Guidelines for documentation
 - Processes for delegation

Appendix B Laboratory Values

Adapted by Jennifer E. Cooke*

The tables in this appendix list some of the most common tests, their normal values, and possible etiologies of abnormal values. Laboratory values are expressed in the *Système Internationale d'Unités* (SI units) that are used in Canada. Conventional units, used in the United States, are presented in parentheses after the SI units. Laboratory values may vary with different techniques or different laboratories. Possible etiologies are presented in alphabetical order. Abbreviations appearing in the tables are defined as follows:

| | | | | | |
|------|---|---|-------|---|--|
| < | = | less than | mcmol | = | micromole |
| > | = | greater than | mcU | = | microunit |
| ≥ | = | greater than or equal to | mEq | = | milliequivalent |
| AU | = | arbitrary unit | mg | = | milligram (10^{-3}) |
| dL | = | decilitre | mL | = | millilitre |
| EU | = | ehrlich unit | mm | = | millimetre |
| fL | = | femtolitre | mm Hg | = | millimetre of mercury |
| g | = | gram | mmol | = | millimole |
| IU | = | international unit | mOsm | = | milliosmole |
| kPa | = | kilopascal | nmol | = | nanomole |
| L | = | litre | ng | = | nanogram (one-billionth of a gram) (10^{-9}) |
| mcg | = | microgram (one-millionth of a gram) (10^{-6}) | pg | = | picogram (one-trillionth of a gram) (10^{-12}) |
| mkat | = | microkatal | pmol | = | picomole |
| mL | = | microlitre | U | = | unit |

TABLE B-1
Serum, Plasma, and Whole Blood Chemistries

| Test | Normal Values | | Possible Etiology | |
|-------------------------|--|--|--|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Acetone | | Diabetic ketoacidosis, high-fat diet, low-carbohydrate diet, starvation | | |
| Quantitative | <200 mcmol/L (<1.16 mg/dL) | | | |
| Qualitative | Negative (Negative) | | | |
| Albumin | 35–50 g/L (3.5–5 g/dL) | Dehydration | Burns, chronic liver disease, malabsorption, malnutrition, nephrotic syndrome, pregnancy | |
| Aldolase | 22–59 mU/L (3–8.2 Sibley-Lehninger U/dL) | Infection, muscle trauma, skeletal muscle disease | Late muscular dystrophy, renal disease | |
| α_1 -Antitrypsin | 0.85–2.13 g/L (85–213 mg/dL) | Acute and chronic inflammation and infection, arthritis, malignancy, stress syndrome, thyroid infections | Chronic lung disease (early onset of emphysema), malnutrition, nephrotic syndrome | |
| α_1 -Fetoprotein | <40 mcg/L (<40 ng/mL) | Cancers of testes and ovaries, carcinoma of liver, neural tube defects or multiple pregnancies in pregnant women | In pregnant women, trisomy 21 or fetal distress/death | |

*Adapted from Lewis, S. M., McLean Heitkemper, M., Dirksen, S. R., Goldworthy, S., Barry, M.A., & Goodridge, D. (2010). *Medical-surgical nursing in Canada* (2nd Canadian ed.). Toronto: Elsevier Canada.

TABLE B-1
Serum, Plasma, and Whole Blood Chemistries—cont'd

| Test | Normal Values | | Possible Etiology | |
|--|--|---|---|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Ammonia | 6–47 mmol/L (10–80 mcg/dL) | Gastrointestinal bleeds, hepatic encephalopathy, portal hypertension, severe liver disease | | |
| Amylase | 30–220 U/L (60–120 Somogyi units/dL) | Acute and chronic pancreatitis, mumps (salivary gland disease), perforated ulcers | Acute alcoholism, cirrhosis of liver, extensive destruction of pancreas | |
| Ascorbic acid | 23–85 mmol/L (0.4–1.5 mg/dL) | Excessive ingestion of vitamin C | Connective tissue disorders, hepatic disease, renal disease, rheumatic fever, vitamin C deficiency | |
| B-type natriuretic peptide | <100 ng/L (<100 pg/mL) | Heart failure, myocardial infarction, hypertension, cor pulmonale | | |
| Bicarbonate | 21–28 mmol/L (21–28 mEq/L) | Chronic use of loop diuretics, compensated respiratory acidosis, metabolic alkalosis | Acute renal failure, compensated respiratory alkalosis, diarrhea, metabolic acidosis | |
| Bilirubin | | Biliary obstruction, hemolytic anemia, impaired liver function, pernicious anemia, prolonged fasting | | |
| Total | 5.1–17 mmol/L (0.3–1.0 mg/dL) | | | |
| Indirect | 3.4–12 mmol/L (0.2–0.8 mg/dL) | | | |
| Direct | 1.7–5.1 mmol/L (0.1–0.3 mg/dL) | | | |
| Blood gases* | | | | |
| Arterial pH | 7.35–7.45 (same as SI units) | Alkalosis | Acidosis | |
| Venous pH | 7.31–7.41 (same as SI units) | Alkalosis | Acidosis | |
| Arterial PCO ₂ | 35–45 mm Hg (same as SI units) | Compensated metabolic alkalosis, respiratory acidosis | Compensated metabolic acidosis, respiratory alkalosis | |
| Arterial PO ₂ | 80–100 mm Hg (same as SI units) | Administration of high concentration of oxygen | Chronic lung disease, decreased cardiac output | |
| Venous PO ₂ | 40–50 mm Hg (same as SI units) | | | |
| Calcium | 2.25–2.75 mmol/L (9–10.5 mg/dL) | Acute osteoporosis, hyperparathyroidism, multiple myeloma, vitamin D intoxication | Acute pancreatitis, hypoparathyroidism, liver disease, malabsorption syndrome, renal failure, vitamin D deficiency | |
| Calcium, ionized | 1.05–1.30 mmol/L (4.5–5.6 mg/dL) | | | |
| Carbon dioxide (CO ₂ content) | 21–28 mmol/L (21–28 mEq/L) | Same as bicarbonate | | |
| β-Carotene | 1.4–4.7 mmol/L (75–253 mcg/dL) | Cystic fibrosis, hypothyroidism, pancreatic insufficiency | Dietary deficiency, malabsorption disorders | |
| Chloride | 98–106 mmol/L (98–106 mEq/L) | Corticosteroid therapy, dehydration, excessive infusion of normal saline, metabolic acidosis, respiratory alkalosis, uremia | Addison's disease, heart failure, diarrhea, metabolic alkalosis, overhydration, respiratory acidosis, SIADH (syndrome of inappropriate antidiuretic syndrome), vomiting | |
| Cholesterol | <5.2 mmol/L (<200 mg/dL) age dependent | Biliary obstruction, cirrhosis, hypothyroidism, hyperlipidemia, idiopathic hypercholesterolemia, renal disease, uncontrolled diabetes | Corticosteroid therapy, extensive liver disease, hyperthyroidism, malnutrition | |
| HDL (high-density lipoproteins) | | | | |
| Male | >0.75 mmol/L (>45 mg/dL) | | | |
| Female | >0.91 mmol/L (>55 mg/dL) | | | |
| LDL (low-density lipoproteins) | <3.37 mmol/L (<60–180 mg/dL) | | | |
| Cholinesterase (RBC) | 5–10 U/L (same as SI units) | Exercise, sickle cell disease | Acute infections, insecticide intoxication, liver disease, muscular dystrophy | |
| Pseudocholinesterase (serum) | 8–18 U/mL (same as SI units) | | | |
| Copper | 11–22 mmol/L (70–140 mcg/dL) | Cirrhosis, contraceptive use by female patient | Wilson's disease | |

*Because arterial blood gases are influenced by altitude, the value for PO₂ decreases as altitude increases. The lower value is normal for an altitude of 1.6 km (1 mile).

TABLE B-1

Serum, Plasma, and Whole Blood Chemistries—cont'd

| Test | Normal Values | | Possible Etiology | |
|--|--|---|--|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Cortisol | 8 AM: 138–635 nmol/L
(5–23 mcg/dL)
8 PM: <83–359 nmol/L
(3–13 mcg/dL) | Adrenal adenoma, Cushing's syndrome, hyperthyroidism, pancreatitis, stress | Addison's disease, adrenal insufficiency, hypopituitary states, hypothyroidism, liver disease | |
| Creatine | 15.3–76.3 mcmol/L
(0.2–1.0 mg/dL) | Active rheumatoid arthritis, biliary obstruction, hyperthyroidism, renal disorders, severe muscle disease | Diabetes mellitus | |
| Creatine kinase (CK) | | | | |
| Male | 55–170 U/L (same as SI units) | Brain damage, exercise, musculoskeletal injury or disease, myocardial infarction, numerous intramuscular injections, severe myocarditis | | |
| Female | 30–135 U/L (same as SI units) | Acute myocardial infarction | | |
| CK-MB (CK-2) | Male: 2–6 mcg/L (2–6 ng/mL)
Female: 2–5 mcg/L (2–5 ng/mL) | | | |
| CK mass fraction | <0.05 fraction of total CK | | | |
| Creatinine | | Severe renal disease | Diseases with decreased muscle mass (e.g., muscular dystrophy, myasthenia gravis) | |
| Male | 53–106 mcmol/L (0.6–1.2 mg/dL) | | | |
| Female | 44–97 mcmol/L (0.5–1.1 mg/dL) | | | |
| Ferritin (serum) | | Anemia of chronic disease (infection, inflammation, liver disease), sideroblastic anemia | Iron-deficiency anemia, severe protein deficiency | |
| Male | 12–300 mcg/L (12–300 ng/mL) | | | |
| Female | 10–150 mcg/L (10–150 ng/mL) | | | |
| Folic acid (folate) | 11–57 nmol/L (5–25 ng/mL) | Hypothyroidism, pernicious anemia | Alcoholism, hemolytic anemia, inadequate diet, malabsorption syndrome, malnutrition, megaloblastic anemia | |
| γ -Glutamyltranspeptidase (GGT) | 8–38 IU/L (same as SI units) | Cholestasis, <i>Cytomegalovirus</i> infection, Epstein-Barr, liver disease, myocardial infarction, pancreatitis | | |
| Glucose, fasting | 4–6 mmol/L (70–110 mg/dL) | Acute stress, cerebral lesions, Cushing's syndrome, diabetes mellitus, hyperthyroidism, pancreatic insufficiency | Addison's disease, hepatic disease, hypothyroidism, insulin overdosage, pancreatic tumour, pituitary hypofunction, post dumping syndrome | |
| 2-Hour oral glucose tolerance testing (OGTT) | | Diabetes mellitus | Hyperinsulinism | |
| Fasting | 4–6 mmol/L (70–110 mg/dL) | | | |
| 1 hour | <11.1 mmol/L (<200 mg/dL) | | | |
| 2 hours | <7.8 mmol/L (<140 mg/dL) | | | |
| Haptoglobin | 0.5–2.2 g/L (50–220 mg/dL) | Acute myocardial infarction, infectious and inflammatory processes, malignant neoplasms | Chronic liver disease, hemolytic anemia, mononucleosis, systemic lupus erythematosus, toxoplasmosis, transfusion reactions | |
| Homocysteine | 4–14 mcmol/L (0.54–1.9 mg/L) | Cardiovascular disease, cerebrovascular disease, peripheral vascular disease, cystinurea, vitamin B ₆ or B ₁₂ deficiency, folate deficiency, malnutrition | | |
| Insulin | 43–186 pmol/L (6–26 mcU/mL) | Acromegaly, adenoma of islet cells, obesity, untreated mild case of type 2 diabetes | Diabetes mellitus, obesity | |
| Iron | | Excessive red blood cell destruction, hemochromatosis, massive transfusion | Anemia of chronic disease, iron-deficiency anemia | |
| Male | 14–32 mcmol/L (80–180 mcg/dL) | | | |
| Female | 11–29 mcmol/L (60–160 mcg/dL) | | | |

TABLE B-1
Serum, Plasma, and Whole Blood Chemistries—cont'd

| Test | Normal Values | | Possible Etiology | |
|------------------------------------|---|---|--|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Total iron-binding capacity (TIBC) | 45–82 $\mu\text{mol/L}$ (250–460 mcg/dL) | Iron-deficient state, oral contraceptive use, polycythemia | Cancer, chronic infections, pernicious anemia, uremia | |
| Lactic acid | 0.6–2.2 mmol/L (5–20 mg/dL) | Acidosis, heart failure, severe liver disease, shock, tissue ischemia | | |
| Lactic dehydrogenase (LDH) | 100–190 U/L (same as SI units) | Heart failure, hemolytic disorders, hepatitis, metastatic cancer of liver, myocardial infarction, pernicious anemia, pulmonary embolus and infarction, skeletal muscle damage | | |
| Lactic dehydrogenase isoenzymes | | | | |
| LDH ₁ | 0.17–0.27 (17%–27%) | Myocardial infarction, pernicious anemia, strenuous exercise | | |
| LDH ₂ | 0.27–0.37 (27%–37%) | Exercise, pulmonary embolus, sickle cell crisis | | |
| LDH ₃ | 0.18–0.25 (18%–25%) | Malignant lymphoma, pulmonary embolus | | |
| LDH ₄ | 0.03–0.08 (3%–8%) | Systemic lupus erythematosus, pancreatitis, pulmonary infarction, renal disease | | |
| LDH ₅ | 0.0–0.05 (0%–5%) | Heart failure, hepatitis, pulmonary embolus and infarction, skeletal muscle damage, strenuous exercise | | |
| Lipase | 0–160 U/L (same as SI units) | Acute and chronic pancreatitis, hepatic disorders, pancreatic disorder (cancer, pseudocyst), perforated peptic ulcer, salivary gland inflammation or tumour | | |
| Magnesium | 0.65–1.05 mmol/L (1.3–2.1 mEq/L) | Addison's disease, hypothyroidism, renal failure | Chronic alcoholism, hyperparathyroidism, hyperthyroidism, hypoparathyroidism, malnutrition, severe malabsorption | |
| Myoglobin | <90 mcg/L (same as SI units) | Myocardial infarction, myositis, malignant hyperthermia, muscular dystrophy, skeletal muscle ischemia or trauma, rhabdomyolysis, seizures | | |
| Osmolality | 285–295 mmol/kg (285–295 mOsm/kg) H_2O | Chronic renal disease, dehydration, diabetes mellitus, hypernatremia, shock | Addison's disease, diuretic therapy, hyponatremia, overhydration | |
| Oxygen saturation | | Increased inspired oxygen, polycythemia vera | | |
| Arterial | $\geq 95\%$ (same as SI units) | | Anemia, cardiac decompensation, decreased inspired oxygen, respiratory disorders | |
| Venous | 60–80% (same as SI units) | | | |
| pH | See Blood gases | | | |
| Phenylalanine | 0–121 $\mu\text{mol/L}$ (0–2 mg/dL) | Phenylketonuria | | |
| Phosphatase, acid | 2.2–10.5 U/L (0.13–0.63 U/L – Roy, Brower, Hayden 37°C) | Advanced Paget's disease, cancer of prostate, hyperparathyroidism | | |
| Phosphatase, alkaline (ALP) | 0.5–2.0 mcat/L (30–120 U/L) | Bone diseases, cirrhosis, malignancy of liver/bone, marked hyperparathyroidism, obstruction of biliary system, rickets | Excessive vitamin D ingestion, hypothyroidism, milk-alkali syndrome | |
| Phosphorus, inorganic | 0.97–1.45 mmol/L (3.0–4.5 mg/dL) | Bone metastasis, healing fractures, hypoparathyroidism, hypocalcemia, renal disease, vitamin D intoxication | | |

Continued

TABLE B-1

Serum, Plasma, and Whole Blood Chemistries-cont'd

| Test | Normal Values | | Possible Etiology | |
|---|--------------------------------------|---|--|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Potassium | 3.5–5.0 mmol/L (3.5–5.0 mEq/L) | Acute or chronic renal failure, Addison's disease, dehydration, diabetic ketosis, excessive dietary/IV intake, massive tissue destruction, metabolic acidosis | Burns, Cushing's syndrome, deficient dietary or intravenous intake, diarrhea (severe), diuretic therapy, gastrointestinal fistula, insulin administration, pyloric obstruction, starvation, vomiting | |
| Prostate-specific antigen (PSA) | <4 mcg/L (<4 ng/mL) | Benign prostatic hypertrophy, prostate cancer, prostatitis | | |
| Proteins | | Burns, cirrhosis (globulin fraction), dehydration | Congenital agammaglobulinemia, increased capillary permeability, inflammatory disease, liver disease, malabsorption, malnutrition | |
| Total | 64–83 g/L (6.4–8.3 g/dL) | | | |
| Albumin | 35–50 g/L (3.5–5 g/dL) | | | |
| Globulin | 23–34 g/L (2.3–3.4 g/dL) | | | |
| Albumin/globulin ratio | 1.5:1–2.5:1 (same as SI units) | Multiple myeloma (globulin fraction), shock, vomiting | Malnutrition, nephrotic syndrome, proteinuria, renal disease, severe burns | |
| Renin | | Renal hypertension, salt-losing gastrointestinal disease (vomiting/diarrhea), volume decrease (e.g., hemorrhage) | Increased salt intake, primary aldosteronism | |
| Upright position | 0.03–1.2 ng/L/sec (0.1–4.3 mg/mL/hr) | | | |
| Sodium | 135–145 mmol/L (135–145 mEq/L) | Corticosteroid therapy, dehydration, impaired renal function, increased sodium intake in diet/IV, primary aldosteronism | Addison's disease, decreased sodium intake in dietary or intravenous intake, diabetic ketoacidosis, diuretic therapy, excessive loss from gastrointestinal tract, excessive perspiration, water intoxication | |
| Testosterone | | | | |
| Male | 9.75–38 nmol/L (280–1080 ng/dL) | Adrenal hyperplasia, adrenal or pituitary tumours, testicular tumours | Hypofunction of testes | |
| Female | 0.52–2.43 nmol/L (<70 ng/dL) | Polycystic ovary, virilizing tumours | | |
| T ₄ (thyroxine), total | 64–154 nmol/L (5–12 mcg/dL) | Hyperthyroidism, thyroiditis | Cretinism, hypothyroidism, myxedema | |
| T ₄ (thyroxine), free | 10–36 pmol/L (0.8–2.8 ng/dL) | Hyperthyroidism, metastatic neoplasms | Hypothyroidism, pregnancy | |
| T ₃ uptake | 24–34 AU (24%–34%) | | | |
| T ₃ (triiodothyronine) | 1.2–3.4 nmol/L (70–205 ng/dL) | Hyperthyroidism | Hypothyroidism | |
| Thyroid-stimulating hormone (TSH) | 2–10 mU/L (2–10 mcU/L) | Graves' disease, myxedema, primary hypothyroidism | Secondary hypothyroidism | |
| Transaminases | | | | |
| Serum glutamic oxaloacetic transferase (SGOT) or aspartate aminotransferase (AST) | 0–0.58 mkat/L (0–35 U/L) | Acute hepatitis, liver disease, myocardial infarction, pulmonary infarction | | |
| Serum glutamate pyruvate transferase (SGPT) or alanine aminotransferase (ALT) | 4–36 U/L (Same as SI units) | Liver disease, shock | | |
| Triglycerides | | Diabetes mellitus, hyperlipidemia, hypothyroidism, liver disease | Hyperthyroidism, malabsorption syndrome, malnutrition | |
| Male | 0.45–1.81 mmol/L (40–160 mg/dL) | | | |
| Female | 0.40–1.52 mmol/L (35–135 mg/dL) | | | |
| Troponin T (cTnT): | <0.2 mcg/L (<0.2 ng/mL) | Cardiac muscle damage, (myocardial infarction, myocarditis or pericarditis), chronic renal failure, multiorgan failure, severe heart failure | | |
| Troponin I (cTnI) | <0.03 mcg/L (<0.3 ng/mL) | | | |

TABLE B-1
Serum, Plasma, and Whole Blood Chemistries—cont'd

| Test | Normal Values | | Possible Etiology | |
|-------------------------|-----------------------------------|--|---|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Urea nitrogen (BUN) | 3.6–7.1 mmol/L (10–20 mg/dL) | Burns, dehydration, gastrointestinal bleeds, increase in protein catabolism (fever, stress), renal disease, shock, urinary tract infection | Fluid overload, malnutrition, severe liver damage, SIADH | |
| Uric acid | | Alcoholism, eclampsia, gout, gross tissue destruction, high-protein weight reduction diet, leukemia, multiple myeloma, renal failure | Administration of uricosuric drugs | |
| Male | 0.24–0.51 mmol/L (4.0–8.5 mg/dL) | | | |
| Female | 0.16–0.43 mmol/L (2.7–7.3 mg/dL) | | | |
| Vitamin A | 0.52–2.09 mcmol/L (15–60 mcg/dL) | Excess ingestion of vitamin A | Vitamin A deficiency | |
| Vitamin B ₁₂ | 118–701 pmol/L (160–950 pg/mL) | Chronic myeloid leukemia | Malabsorption syndrome, pernicious anemia, strict vegetarianism, total or partial gastrectomy | |
| Zinc | 11.5–18.5 mcmol/L (75–120 mcg/dL) | | Alcoholic cirrhosis | |

TABLE B-2
Hematology

| Test | Normal Values | | Possible Etiology | |
|---|--|--|---|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Bleeding time (IVY) | 1–9 min | Aspirin ingestion, clotting factor deficiency, defective platelet function, thrombocytopenia, vascular disease, von Willebrand's disease | | |
| Activated partial thromboplastin time (APTT) | 30–40 sec* (same as SI units) | Deficiency of factors I, II, V, VIII, IX and X, XI, XII; hemophilia; heparin therapy; liver disease | | |
| Partial thromboplastin time (PTT) | 60–70 sec (same as SI units) | Same etiology as for APTT | | |
| Automated coagulation time or activated clotting time (ACT) | 70–120 sec (same as SI units) | Same etiology as for APTT | | |
| Prothrombin time (Protime, PT) | 11–12.5 sec* (same as SI units) | Deficiency of factors I, II, V, VII, and X; liver disease; vitamin K deficiency; warfarin therapy | | |
| International normalized ratio (INR) | 0.81–1.2 (same as SI units) | Same etiology as for PT | | |
| Thrombin Time | 8–12 sec (same as SI units) | Disseminated intravascular coagulation (DIC), increased tendency to bleed | | |
| Fibrinogen | 2–4 g/L (200–400 mg/dL) | Burns (after first 36 hr), inflammatory disease | Burns (during first 36 hr), DIC, severe liver disease | |
| Fibrin split (degradation) products | <10 mg/L (<10 mcg/mL) | Acute DIC, massive hemorrhage, massive trauma, primary fibrinolysis | | |
| D-Dimer | <250 mcg/L (<250 ng/mL) | Deep vein thrombosis, DIC, myocardial infarction, unstable angina | | |
| Erythrocyte count [†] (altitude dependent) | | Dehydration, high altitudes, polycythemia vera, severe diarrhea | Anemia, leukemia, post hemorrhage | |
| Male | 4.7–6.1 × 10 ¹² /L (4.7–6.1 × 10 ⁶ /mCL) | | | |
| Female | 4.2–5.4 × 10 ¹² /L (4.2–5.4 × 10 ⁶ /mCL) | | | |

*Patients receiving anticoagulant therapy:

APTT: 1.5–2.5 times control value in seconds

PT: 1.5–2.0 times control value in seconds

[†]Components of complete blood count (CBC).

TABLE B-2
Hematology-cont'd

| Test | Normal Values | | Possible Etiology | |
|---|--|--|---|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Mean corpuscular volume (MCV) | 80–95 mm ³ (same as SI units) | Folic acid and vitamin B ₁₂ deficiency, liver disease, macrocytic anemia | Microcytic anemia | |
| Mean corpuscular hemoglobin (MCH) | 27–31 pg (same as SI units) | Macrocytic anemia | Microcytic anemia | |
| Mean corpuscular hemoglobin concentration (MCHC) | 320–360 g/L (32–36 g/dL) (32%–36%) | Intravascular hemolysis, spherocytosis | Hypochromic anemia | |
| Erythrocyte sedimentation rate (ESR), Westergren | | <i>Moderate increase:</i> acute hepatitis, myocardial infarction, rheumatoid arthritis | Malaria, severe liver disease, sickle cell anemia | |
| Male | <50 yr <15 mm/hr (same as SI units)
>50 yr <20 mm/hr (same as SI units) | <i>Marked increase:</i> acute and severe bacterial infections, malignancies, pelvic inflammatory disease | | |
| Female | <50 yr <20 mm/hr (same as SI units)
>50 yr <30 mm/hr (same as SI units) | | | |
| Hematocrit (altitude dependent) [†] | | Dehydration, high altitudes, polycythemia | Anemia, bone marrow failure, hemorrhage, leukemia, overhydration | |
| Male | 0.42–0.52 volume fraction (42%–52%) | | | |
| Female | 0.37–0.47 volume fraction (37%–47%) | | | |
| Hemoglobin (altitude dependent) [†] | | Chronic obstructive pulmonary disease, high altitudes, polycythemia | Anemia, hemorrhage | |
| Male | 135–180 g/L (13.5–18 g/dL) | | | |
| Female | 120–160 g/L (12–16 g/dL) | | | |
| Hemoglobin, glycosylated or glycated (HbA _{1c} [A _{1c}]) | Less than 6% (adult without diabetes) | Nondiabetic hyperglycemia, poorly controlled diabetes mellitus | Chronic blood loss, chronic renal failure, pregnancy, sickle cell anemia | |
| Red cell distribution width (RDW) | 11%–14.5% (same as SI units) | | Anisocytosis, macrocytic anemia, microcytic anemia | |
| Platelet count (thrombocytes) | 150–400 × 10 ⁹ /L (150,000–400,000 mm ³) | Acute infections, chronic granulocytic leukemia, chronic pancreatitis, cirrhosis, collagen disorders, polycythemia, post splenectomy | Acute leukemia, cancer chemotherapy, DIC, hemorrhage, infection, systemic lupus erythematosus, thrombocytopenic purpura | |
| Reticulocyte count(manual) | 0.5%–2% of RBC (same as SI units) | Hemolytic anemia, polycythemia vera | Hypoproliferative anemia, macrocytic anemia, microcytic anemia | |
| White blood cell (WBC) count [†] | 5–10 × 10 ⁹ /L (5000–10,000 mm ³) | Inflammatory and infectious processes, leukemia | Aplastic anemia, autoimmune diseases, overwhelming infection, side effects of chemotherapy and irradiation | |
| WBC differential | | | | |
| Segmented neutrophils | 2.5–7.5 × 10 ⁹ /L (62%–68%) | Bacterial infections, collagen diseases, Hodgkin's disease | Aplastic anemia, viral infections | |
| Band neutrophils | 0–1 × 10 ⁹ /L (0%–9%) | Acute infections | | |
| Lymphocytes | 0.1–0.4 × 10 ⁹ /L (1000–4000 mm ³) (20%–40%) | Chronic infections, lymphocytic leukemia, mononucleosis, viral infections | Corticosteroid therapy, whole body irradiation | |
| Monocytes | 0.02–0.07 × 10 ⁹ /L (100–700 mm ³) (2%–8%) | Acute infections, chronic inflammatory disorders, Hodgkin's disease, malaria, monocytic leukemia | | |
| Eosinophils | 0.01–0.04 × 10 ⁹ /L (50–100 mm ³) (1%–4%) | Allergic reactions, eosinophilic and chronic granulocytic leukemia, Hodgkin's disease, parasitic disorders | Corticosteroid therapy | |
| Basophils | 0.0–0.01 × 10 ⁹ /L (25–100 mm ³) (0.5%–1%) | Hypothyroidism, myeloproliferative diseases, ulcerative colitis | Hyperthyroidism, stress | |
| Sickle cell solubilitytest | Negative (Negative) | Sickle cell anemia | | |

TABLE B-3
Serology-Immunology

| Test | Normal Values | | Possible Etiology | |
|---|--|---|--|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Antinuclear antibody (ANA) | Negative at 1:40 dilution (same as SI units) | Chronic hepatitis, rheumatoid arthritis, scleroderma, systemic lupus erythematosus (SLE) | | |
| Anti-DNA antibody | Negative <70 U/mL (same as SI units) | SLE | | |
| Anti-RNP (ribonucleoprotein) | Negative (Negative) | Mixed connective tissue disease, scleroderma, rheumatoid arthritis, Sjögren's syndrome, SLE | | |
| Anti-Smith (Smith) | Negative (Negative) | SLE | | |
| Antistreptolysin-O (ASO) | ≤160 Todd units/mL (same as SI units) | Acute glomerulonephritis, rheumatic fever, streptococcal infection | | |
| C-reactive protein (CRP) | <10 mg/L (<1.0 mg/dL) | Acute infections, any inflammatory condition (e.g., acute rheumatic fever/arthritis), widespread malignancy | | |
| Carcinoembryonic antigen (CEA) | 5 mcg/L (5 ng/mL) | Carcinomas of colon, liver, pancreas; chronic cigarette smoking; inflammatory bowel disease; other cancers | | |
| Complement assay components | | | Acute glomerulonephritis, rheumatoid arthritis, serum sickness, subacute bacterial endocarditis, SLE | |
| Total C3 | 75–160 k/units/L (75–160 U/mL) | | | |
| C4 | 0.55–1.2 g/L (55–120 mg/dL) | | | |
| Direct antihuman globulin test (DAT) or direct Coombs' test | Negative (Negative) (No agglutination) | Acquired hemolytic anemia, drug reactions, hemolytic disease of the newborn, transfusion reactions | | |
| Fluorescent treponemal antibody absorption (FTAAbs) | Negative (Nonreactive) | Syphilis | | |
| Hepatitis A antibody | Negative (Negative) | Hepatitis A | | |
| Hepatitis B surface antigen (HBsAg) | Negative (Negative) | Hepatitis B | | |
| Hepatitis C antibody | Negative (Negative) | Hepatitis C | | |
| Immunoglobulins | | | | |
| IgA | 0.85–3.85 g/L (85–385 mg/dL) | Autoimmune disorders, chronic infection, chronic liver disease, IgA myeloma, rheumatoid arthritis | Burns, hereditary telangiectasia, malabsorption syndromes | |
| IgD | Minimal | Chronic infection, connective tissue disease | | |
| IgE | Minimal | Anaphylactic shock, atopic disease (allergies), parasite infections | | |
| IgG | 5.65–17.65 g/L (565–1765 mg/dL) | Hepatitis, IgG monoclonal gammopathy, infections—acute and chronic, SLE | Acquired deficiencies, burns, congenital deficiencies, immunosuppression, nephrotic syndromes | |
| IgM | 0.55–3.75 g/L (55–375 mg/dL) | Acute infections, liver disease, rheumatoid arthritis | Congenital and acquired antibody deficiencies, lymphocytic leukemia, protein-losing enteropathies | |
| Monospot or monotest | Negative (<1:28 titre) | Infectious mononucleosis | | |
| Rheumatoid factor (RA factor) | 0.2 kU/L (0.2 U/mL) nephelometric method | Rheumatoid arthritis, Sjögren's syndrome, SLE | | |
| RPR (rapid plasma reagin) test | <1:20 titre agglutination method | | | |
| | Negative or nonreactive (same as SI units) | Febrile diseases, IV drug abuse, leprosy, malaria, rheumatoid arthritis, syphilis, SLE | | |

Continued

TABLE B-3

Serology-Immunology-cont'd

| Test | Normal Values | | Possible Etiology | |
|--|--|---|-------------------|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| VDRL (Venereal Disease Research Laboratory) test | Negative or nonreactive (same as SI units) | Syphilis | | |
| Thyroid antibodies | Titre <1:100 (same as SI units) | Early hypothyroidism, Graves' disease, Hashimoto's thyroiditis, pernicious anemia, SLE, thyroid carcinoma | | |

TABLE B-4

Urine Chemistry

| Test | specimen | Normal Values | | Possible Etiology | |
|---|----------|---|--|---|--|
| | | SI Units (Conventional Units) | Higher | Lower | |
| Acetone (ketones) | Random | Negative (Negative) | Diabetes mellitus, high-fat and low-carbohydrate diets, starvation states | | |
| Aldosterone | 24 hr | 6–72 nmol/24 hr (2–26 mcg/24 hr) (depends on urinary sodium) | Primary aldosteronism: adrenocortical tumours
Secondary aldosteronism: cardiac failure, cirrhosis, large dose of ACTH, salt depletion | Adrenocorticotrophic hormone (ACTH) deficiency, Addison's disease, corticosteroid therapy | |
| Amylase | 24 hr | Up to 5000 Somogyi units/24 hr OR 6.5–48.1 units/hr | Acute pancreatitis | | |
| Bence Jones protein | Random | Negative (Negative) | Biliary duct obstruction, multiple myeloma | | |
| Bilirubin | Random | Negative (Negative) | Hepatitis | | |
| Calcium | 24 hr | 6.2 mmol/day (<250 mg/day) | Bone tumour, hyperparathyroidism, milk-alkali syndrome | Hypoparathyroidism, malabsorption of calcium and vitamin D | |
| Catecholamines | 24 hr | | Heart failure, pheochromocytoma, progressive muscular dystrophy | | |
| Epinephrine
Norepinephrine
Chloride | 24 hr | <109 nmol/day (<20 mcg/d)
<590 nmol/day (<100 mcg/d)
110–250 mmol/d (110–250 mEq/d)
<0.5 mmol/d (<30 mcg/d) | Addison's disease | Burns, diarrhea, excess perspiration, menstruation, vomiting | |
| Copper | 24 hr | 0.6 mmol/d (<40 mcg/d) | Cirrhosis, Wilson's disease | | |
| Coproporphyrin | 24 hr | <300 nmol/d (<200 mcg/d) | Lead poisoning, oral contraceptive use, poliomyelitis | | |
| Creatine | 24 hr | | Addison's disease, burns, carcinoma of liver, diabetes, hyperthyroidism, infections, muscular dystrophy, skeletal muscle atrophy | Hypothyroidism | |
| Male
Female
Creatinine | 24 hr | <300 mmol/d (<60 mg/d)
<600 mmol/d (<80 mg/d)
7.1–17.7 mmol/d (0.8–2 g/d) | Anemia, leukemia, muscular atrophy, salmonellosis | Renal disease | |
| Creatinine clearance | 24 hr | 1.42–2.25 mL/sec (85–135 mL/min)
Male
1.78–2.32 mL/sec (107–139 mL/min)
Female
1.45–1.78 mL/sec (87–107 mL/min) | | Renal disease | |

TABLE B-4
Urine Chemistry—cont'd

| Test | specimen | Normal Values | | Possible Etiology | |
|--------------------------------------|----------------|--|--|---|--|
| | | SI Units (Conventional Units) | Higher | Lower | |
| Estriol | 24 hr | | Gonadal or adrenal tumour | Agensis of ovaries, endocrine disturbance, menopause, ovarian dysfunction | |
| Female | | | | | |
| • Ovulation peak | | 104–370 nmol/d (28–100 mcg/d) | | | |
| • Luteal peak | | 81–296 nmol/d (22–80 mcg/d) | | | |
| • Pregnancy | | Up to 166,455 nmol/d (Up to 45,000 mcg/d) | | | |
| • Menopause | | 5.2–72.5 nmol/d (1.4–19.6 mcg/d) | | | |
| Male | | 18–67 nmol/d (5–18 mcg/d) | | | |
| Glucose | Random | Negative (Negative) | Diabetes mellitus, low renal threshold for glucose resorption, physiological stress, pituitary disorders | | |
| Hemoglobin | Random | Negative (Negative) | Extensive burns, glomerulonephritis, hemolytic anemias, hemolytic transfusion reaction | | |
| 5-Hydroxyindole-acetic acid (5-HIAA) | 24 hr | 10–40 mmol/d (2–8 mg/24 hr) | Malignant carcinoid syndrome | | |
| Ketone bodies | Random | Negative (Negative) | Alcoholism, fasting, high-protein diets, marked ketonuria, poorly controlled diabetes mellitus, starvation | | |
| Lead | 24 hr | <0.40 mmol/d (<80 mcg/d) | Lead poisoning | | |
| Metanephrine | 24 hr | <7 mmol/d (<1.3 mg/d) | Pheochromocytoma | | |
| Myoglobin | Random | Negative (Negative) | Crushing injuries, electric injuries, extreme physical exertion | | |
| pH | Random | 4.6–8 (same as SI units)
Average: 6 | Chronic renal failure, compensatory phase of alkalosis, salicylate intoxication, vegetarian diet | Compensatory phase of acidosis, dehydration, emphysema | |
| Phenylpyruvic acid | Random | Negative (Negative) | Phenylketonuria | | |
| Phosphorus, inorganic | 24 hr | 29–42 mmol/d (0.9–1.3 g/d) | Fever, hypoparathyroidism, nervous exhaustion, rickets, tuberculosis | Acute infections, nephritis | |
| Porphobilinogen | Random | Negative (Negative) | Acute intermittent porphyria, liver disorders | | |
| Potassium | 24 hr
24 hr | <8.8 mmol/d (<2 mcg/d)
25–100 mmol/d (25–100 mEq/d) | Chronic renal failure, starvation, Cushing's syndrome, hyperaldosteronism, alkalosis, diuretic therapy | Reduced intake, dehydration, Addison's disease, malnutrition, vomiting, diarrhea, acute renal failure | |
| Protein (dipstick) | Random | Negative (Negative) | Heart failure, nephritis, nephrosis, physiological stress | | |
| Protein (quantitative) | 24 hr | <0.15 g/d (<150 mg/d) | Cardiac failure, inflammatory processes of urinary tract, nephritis, nephrosis, toxemia of pregnancy | | |
| At rest | | 0.05–0.08 g/d (<50–80 mg/d) | | | |
| During exercise | | <0.25 g/d (<250 mg/d) | | | |
| Sodium | 24 hr | 40–250 mmol/d (40–250 mEq/d) | Acute tubular necrosis | Hyponatremia | |
| Specific gravity | Random | 1.005–1.030 (same as SI units) | Albuminuria, dehydration, fever, gastrointestinal losses (vomiting/diarrhea), glycosuria, syndrome of inappropriate antidiuretic hormone (SIADH) | Diabetes insipidus, diuresis, overhydration | |

Continued

TABLE B-4
Urine Chemistry—cont'd

| Test | specimen | Normal Values | Possible Etiology | |
|-----------------------|-----------------|---|---|-----------------------------------|
| | | SI Units (Conventional Units) | Higher | Lower |
| Titrateable acidity | 24 hr | 20–50 mEq/d (same as SI units) | Metabolic acidosis | Metabolic alkalosis |
| Uric acid | 24 hr | 1.48–4.43 mmol/d (250–750 mg/24 hr) | Gout, leukemia | Nephritis |
| Urobilinogen | 24 hr
Random | 0.0–6.8 mcmol/d (0.0–4.0 mg/24 hr)
<0.01–1 EU (same as SI units) | Hemolytic disease, hepatic parenchymal cell damage, liver disease | Complete obstruction of bile duct |
| Uroporphyrins | 24 hr | | Lead poisoning, liver disease, porphyria | |
| Male | | 4–46 mcg/d (same as SI units) | | |
| Female | | 3–22 mcg/d (same as SI units) | | |
| Vanillylmandelic acid | 24 hr | <35 mcmol/d (<6.8 mg/d) | Pheochromocytoma, neuroblastomas | |

TABLE B-5
Gastric Analysis

| Test | Normal Values | Possible Etiology | |
|------------------------|-------------------------------|---|-------------------------------------|
| | SI Units (Conventional Units) | Higher | Lower |
| Basal | | | |
| Free hydrochloric acid | 0.3 mmol/L (0.3 mEq/L) | Hypermotility of stomach | Pernicious anemia |
| Total acidity | 15–45 mmol/L (15–45 mEq/L) | Gastric and duodenal ulcers, Zollinger-Ellison syndrome | Gastric carcinoma, severe gastritis |
| Poststimulation | | | |
| Free hydrochloric acid | 10–130 mmol/L (10–130 mEq/L) | | |
| Total acidity | 20–150 mmol/L (20–150 mEq/L) | | |

TABLE B-6
Fecal Analysis

| Test | Normal Values | Possible Etiology | |
|--------------|--|--|------------------------------|
| | SI Units (Conventional Units) | Higher | Lower |
| Fecal fat | 7.21 mmol/day (2–6 g/d) | Chronic pancreatic disease, cystic fibrosis, malabsorption syndrome, obstruction of common bile duct, short gut syndrome | |
| Urobilinogen | 51–372 mcmol/100 g of stool (30–220 mg/100 g of stool) | Hemolytic anemias | Complete biliary obstruction |
| Mucus | Negative (Negative) | Mucous colitis, spastic constipation | |
| Pus | Negative (Negative) | Chronic bacillary dysentery, chronic ulcerative colitis, localized abscesses | |
| Blood* | Negative (Negative) | Anal fissures, hemorrhoids, inflammatory bowel disease, malignant tumour, peptic ulcer | |
| Colour | | | |
| Brown | | Various colours depending on diet | |
| Clay | | Biliary obstruction or presence of barium sulphate | |
| Tarry | | More than 100 mL of blood in gastrointestinal tract | |
| Red | | Blood in large intestine | |
| Black | | Blood in upper gastrointestinal tract or iron medication | |

*Ingestion of meat may produce false-positive results. Patient may be placed on a meat-free diet for three days before the test.

TABLE B-7
Cerebrospinal Fluid Analysis

| Test | Normal Values | | Possible Etiology | |
|----------------------------|--|--|--|--|
| | SI Units (Conventional Units) | Higher | Lower | |
| Pressure | <20 cm H ₂ O (same as SI units) | Hemorrhage, intracranial tumour, meningitis | Head injury, spinal tumour, subdural hematoma | |
| Blood | Negative (Negative) | Intracranial hemorrhage | | |
| Cell count (age dependent) | | | | |
| WBC (white blood cells) | 0–5 × 10 ⁶ /L (0–5 cells/mcL) | Inflammation or infections of central nervous system (CNS) | | |
| RBC (red blood cells) | Negative (Negative) | | | |
| Chloride | 115–130 mmol/L (115–130 mEq/L) | Uremia | Bacterial infections of CNS (meningitis, encephalitis) | |
| Glucose | 2.8–4.2 mmol/L (50–75 mg/dL) | Diabetes mellitus, viral infections of CNS | Bacterial infections and tuberculosis of CNS | |
| Protein | | | | |
| Lumbar | 0.15–0.45 g/L (15–45 mg/dL) | Guillain-Barré syndrome, poliomyelitis, traumatic tap | | |
| Cisternal | 0.15–0.25 g/L (15–25 mg/dL) | Syphilis of CNS | | |
| Ventricular | 0.05–0.15 g/L (5–15 mg/dL) | Acute meningitis, brain tumour, chronic CNS infections, multiple sclerosis | | |

Review Question Rationales

Chapter 1

1. **The correct answer is 1.** The *Lalonde Report* shifted emphasis from a medical to a behavioural approach to health. It concluded that the traditional medical approach to health care was inadequate and that “further improvements in the environment, reductions in self-imposed risks, and a greater knowledge of human biology” are necessary to improve the health status of Canadians.
2. **The correct answer is 4.** The *Ottawa Charter for Health Promotion* supported a socioenvironmental approach to health. It identified prerequisites for health: peace, shelter, education, food, income, a stable ecosystem, sustainable resources, social justice, and equity.
3. **The correct answer is 1.** Labonte (1993) categorized the major determinants of health in a socioenvironmental approach as psychosocial risk factors and socioenvironmental risk conditions. Political, social, and cultural forces affect health and well-being directly and indirectly through their influence on personal health behaviours. Socioenvironmental risk conditions can contribute to psychosocial risk factors, which can then result in unhealthy behaviours.
4. **The correct answer is 1.** Given that the determinants of health are broad, healthy public policy must extend beyond traditional health care agencies and government health care departments to other sectors such as agriculture, education, transportation, labour, social services, energy, and housing. Therefore, policymakers in all government sectors and organizations should know the health consequences of their policies.
5. **The correct answer is 2.** Primary prevention includes activities that protect against a disease before signs and symptoms occur. Examples are immunization (to prevent infectious diseases) and reduction of risk factors (such as inactivity, smoking, and exposure to air pollution).
6. **The correct answer is 3.** Rather than focusing only on helping people develop healthy behaviours, health promotion seeks to create healthy public policy, supportive environments, community action, and personal skill. Health promotion is committed to empowerment and community-based health planning and addresses health issues within the context of the social, economic, and political environment. It therefore is political.
7. **The correct answer is 2.** The belief that health is primarily an *individual* responsibility is most congruent with the behavioural approach to health. The behavioural approach places responsibility for health on the individual, thereby favouring health promotion strategies such as education. Strategies are often based on the assumption that if people know the risk factors of disease, they will engage in healthy behaviours.
8. **The correct answer is 3.** Rather than focusing primarily on interventions at the societal level, the population health promotion model advocates that interventions be implemented toward individuals and families, communities, individual sectors of society (such as health care or environmental sectors), and society as a whole.
9. **The correct answer is 2.** Income and social status are the greatest determinants of health. Canadians who live in poverty have poorer health and are more likely to die earlier

and to suffer more illnesses than those with higher incomes, regardless of age, sex, race, culture, and place of residence.

10. **The correct answer is 2.** Health promotion is directed toward increasing the level of well-being and self-actualization.

Chapter 2

1. **The correct answer is 2.** Canada Infoway was created by the First Ministers in 1999 to move the e-health agenda across Canada.
2. **The correct answer is 4.** A number of target groups (e.g., Royal Canadian Mounted Police [RCMP], Aboriginal peoples, members of military services) are covered directly by the Canadian government. People who are moving between provinces or territories are covered under the *Canada Health Act*.
3. **The correct answer is 2.** Public health care is focused on preventive measures and programs that ensure conditions and circumstances to keep people healthy through appropriate screening, assessment, development, monitoring, and support (i.e., public policy).
4. **The correct answer is 1.** The five principles of the *Canada Health Act* are public administration, comprehensiveness, universality, portability, and accessibility.
5. **The correct answer is 3.** Community services are directed at primary and secondary care, located where they live, work, play, and interact. An adult day care centre is a community agency.
6. **The correct answer is 1.** The five levels of health care services are promotive, preventive, curative (diagnosis and treatment), rehabilitative, and supportive (including home care, long-term care, and palliative care).
7. **The correct answer is 3.** Many professional associations have committed to ethical recruitment and retention at the international level to reduce depletion of critically needed health care providers in developing contexts.
8. **The correct answer is 1.** Health care cost accelerators include new technology, new pharmaceuticals, an increase in chronic and new diseases, and changing demographics and expectations.
9. **The correct answer is 2.** Disease prevention services help patients, families, and communities reduce risk factors for disease and injury. Prevention strategies include clinical (screening, immunization), behavioural (lifestyle change, support groups), or environmental (societal pressure for a healthy environment).
10. **The correct answer is 3.** Secondary care involves provision of a specialized medical service by a physician specialist or a hospital on referral from a primary care practitioner. Secondary care deals with patients seeking definitive diagnosis or requiring further diagnostic review.

Chapter 3

1. **The correct answer is 2.** Florence Nightingale, considered to be the founder of modern nursing, spearheaded the movement to improve standards of nursing care in the mid-nineteenth century.
2. **The correct answer is 3.** Marguerite d'Youville formed the Sisters of Charity of Montreal, a Canadian order of nuns, in 1737. They began as a small group of women who pooled their

possessions to form a refuge for the poor and needy and eventually became the first visiting nurses in Canada.

3. **The correct answer is 4.** The first doctoral nursing program was established at the University of Alberta on January 1, 1991.
4. **The correct answer is 3.** As a result of a movement that began in the 1960s, nursing legislation has recently been developed in most provinces and territories to regulate the practice of nurse practitioners.
5. **The correct answer is 1.** A code of ethics defines the principles by which nurses function. The first code of ethics for nursing was developed by the International Council of Nurses (ICN) in 1953 and was adopted by the Canadian Nurses Association (CNA) in 1954. The CNA Code of Ethics was updated most recently in 2008.
6. **The correct answer is 2.** Professional nursing organizations establish education and practice standards for nurses, carry out the regulatory functions of registration and licensure, and discipline members who do not meet the standards. They also serve as the voice of nurses on matters of professional interest and concern, help their members maintain competence through continuing education, and collaborate with other health care professional organizations on matters of mutual interest. They do not monitor unregulated care providers.
7. **The correct answer is 2.** In all provinces and territories, nursing practice acts regulate licensure and the practice of nursing. Each province or territory defines for itself the scope of nursing practice because constitutional responsibility for education and health care rests with individual provinces and territories.
8. **The correct answer is 2.** In all provinces except Ontario and Quebec, provincial nursing associations assume responsibility for defining and monitoring standards.
9. **The correct answer is 3.** Nursing unions are primary participants as the representatives of nurses in particular provinces or territories when new contracts are negotiated.

Chapter 4

1. **The correct answer is 1.** The overall goals of a population health approach are to maintain and improve the health of the entire population and to eliminate health disparities. The population health approach provides a framework for thinking about health and for taking action to improve the health of populations. Action is directed primarily at community levels.
2. **The correct answer is 2.** Public health nursing merges knowledge from the public health sciences with professional nursing theories to safeguard and improve the health of populations in the community.
3. **The correct answer is 3.** Community-based nursing involves acute, chronic, and palliative care of patients and families that enhances their capacity for self-care and promotes autonomy in decision making.
4. **The correct answer is 4.** Vulnerable populations of patients are those who are likely to develop health problems as a result of excess risks, who experience barriers when trying to access to health care services, or who are dependent on others for care.
5. **The correct answer is 4.** Competent care of vulnerable populations does not include offering financial or legal advice.
6. **The correct answer is 2.** Physical, emotional, and sexual abuse, as well as neglect, are major public health problems affecting older adults, women, and children.
7. **The correct answer is 2.** A successful community health nursing practice requires an ability to build relationships with

the community and to be responsive to changes within the community.

8. **The correct answer is 3.** Perinatal classes, infant care, child safety, and cancer screening are just some of the health education programs in which a nurse in community practice may participate as a nurse educator.
9. **The correct answer is 1.** The nurse as consultant provides information and supports participation in health activities. In this role, the nurse responds to inquiries about and makes referrals to community resources.
10. **The correct answer is 1.** The community can be viewed as having three components: locale or structure, the social systems, and the people.

Chapter 5

1. **The correct answer is 4.** A theory is a purposeful set of assumptions or propositions that show relationships between concepts. Theories are useful because they provide a systematic view of explaining, predicting, and prescribing phenomena.
2. **The correct answer is 3.** The drive for early theorizing about nursing practice came from nursing educators, who noted that traditional ways of preparing professional nurses were becoming outdated.
3. **The correct answer is 1.** The nursing process originally involved four steps: assessment, planning, intervention, and evaluation.
4. **The correct answer is 1.** Each conceptual framework attempted to define nursing by creating a theoretical definition for the substance and structure of the key bodies of knowledge needed to understand clinical situations. This knowledge was called the metaparadigm concepts and included person, environment, health care, and nursing care.
5. **The correct answer is 3.** The question confronting early theorists about nursing practice remained as follows: How does a nurse organize and make sense of all available knowledge and apply it intelligently to the challenges that arise in an individual clinical case?
6. **The correct answer is 1.** Kuhn challenged the traditional notion of science as a logical progression of discoveries. He argued that major scientific developments occurred when scientists thought about problems in radically new and different ways.
7. **The correct answer is 1.** The main features of the McGill model were "a focus on health rather than illness and treatment, on all family members rather than the patient alone, on family goals rather than on the nurse's, and on family strengths rather than their deficits."
8. **The correct answer is 2.** Peplau defined the essence of nursing as the interpersonal relationship between the nurse and the patient. She viewed this relationship as interactive and therapeutic, in which the goal was to support the patient to achieve independent living.
9. **The correct answer is 2.** Canadian theorist Evelyn Adam articulated the essence of nursing as a helping process. From her perspective, the nurse played a complementary-supplementary role in supporting the patient's strength, knowledge, and will.
10. **The correct answer is 2.** Systems theory accounted for the whole of an entity (the system) and its component parts (subsystems), as well as the interactions between the parts and the whole.

11. **The correct answer is 2.** Parse's nursing model does not articulate goals for nursing in the traditional sense of defining health; instead, it relies on the notion of people in a continuous process of making choices and changing health care priorities.

Chapter 6

1. **The correct answer is 4.** The first provincially approved doctoral nursing program was established at the University of Alberta Faculty of Nursing in 1991.
2. **The correct answer is 4.** Carper (1978) described empirics as "knowledge that is systematically organized into general laws and theories for the purpose of describing, explaining and predicting phenomena of special concern to the discipline of nursing."
3. **The correct answer is 1.** The quantitative research approach is characterized by systematic, orderly procedures that seek to limit the possibility of error and minimize the likelihood that any bias or opinion by the researcher might influence the results of research and, thus, the knowledge gained.
4. **The correct answer is 3.** Ethnography is chosen if the research question leads to the study of behaviour within a specific group or culture. Ethnography involves the observation and description of behaviour in social settings. It is derived from anthropology, in which it provides the means to study the culture of groups of people.
5. **The correct answer is 2.** Subjectivity from the participants' perspective is sought in qualitative research. Because of the nature of the data, rich with personal experience and example, the research is usually reported in a literary style, similar to storytelling.
6. **The correct answer is 4.** Quasi-experimental designs are an adaptation of the experimental design. Measurement of outcome variables occurs before and after an intervention (treatment) is given to research subjects. As the design incorporates measurement in a structured way, it is a quantitative design.
7. **The correct answer is 2.** The sample in a survey design should be representative of the population so that generalizations can be made on the basis of the sample data.
8. **The correct answer is 3.** Naming other participants is not required for informed consent. The consent form must describe the purpose of the study, the role of the subjects, types of data that are to be obtained, how the data are obtained, the duration of the study, subject selection, procedures, risks to the subject, potential benefits, alternatives to participation, and contact information.
9. **The correct answer is 3.** A quasi-experimental research design is one in which groups are formed and the conditions are controlled, but the subjects are not randomly assigned to a control group or treatment conditions.
10. **The correct answer is 4.** As well as using knowledge based on systematic research studies, evidence-informed practice also takes into account a nurse's clinical experience, practice trends, and patient preferences.
2. **The correct answer is 4.** *Justice* refers to fairness. The term is often used during discussions about resources. The question in this situation is how to determine the just distribution of resources. What constitutes a fair distribution of resources may not always be clear.
3. **The correct answer is 3.** *Maleficence* refers to harm or hurt; thus, *nonmaleficence* is the avoidance of harm or hurt. In health care ethics, ethical practice involves not only the will to do good but also the equal commitment to do no harm.
4. **The correct answer is 1.** *Beneficence* refers to taking positive actions to help other people. Commitment to beneficence helps to guide difficult decisions wherein the benefits of a treatment may be challenged by risks to the patient's well-being or dignity.
5. **The correct answer is 4.** *Autonomy* refers to a person's independence. Autonomy represents an agreement to respect another person's right to determine a course of action. Respect for a patient's autonomy is fundamental to the practice of health care. It is why patients are included in all aspects of decision making regarding their care.
6. **The correct answer is 2.** The value of autonomy is to respect a patient's choice or self-determination.
7. **The correct answer is 3.** Advocacy calls for the nurse to allow patients' opinions to be heard (give patients a voice) and to speak out for those who cannot speak.
8. **The correct answer is 3.** The nurse does not make decisions for the patient. Advocating for the patient includes protecting the patient's right to choice by providing information, obtaining informed consent for all nursing care, and respecting patients' decisions.
9. **The correct answer is 1.** Relational ethics explores the notion of relationships as a central activity of human behaviour. Scholars who write about relational ethics maintain that relationship is central to everything that nurses do and reflects a way of "being," displayed in everyday interactions rather than a mode of decision making.
10. **The correct answer is 2.** Each step in the processing of an ethical dilemma resembles steps in critical thinking. The nurse begins by gathering information and moves through assessment and identification of the problem, planning a solution, implementation of a solution, and evaluation of the results.

Chapter 8

Chapter 7

1. **The correct answer is 3.** By understanding their personal values, nurses better understand their patients' and colleagues' values. In "value conflict," personal values are at odds with those of a patient, a colleague, or an institution. Values clarification plays a major role in resolving these dilemmas.
1. **The correct answer is 1.** Statute law is created by elective legislative bodies such as Parliament and provincial or territorial legislatures. Examples of provincial statutes are the nursing practice acts throughout the country, which describe and define nursing practice within each province.
2. **The correct answer is 1.** Any intentional physical contact such as treating a patient without the patient's consent is considered battery.
3. **The correct answer is 2.** The inappropriate or unjustified use of restraints (e.g., by confining a person to an area, using physical or chemical restraints) may be viewed as false imprisonment.
4. **The correct answer is 4.** Negligence in nursing is conduct that falls below a standard of care established by law. No intent is needed for negligence to occur. It is characterized chiefly by inadvertence, thoughtlessness, or inattention. Therefore, failing to raise the side rails when they are ordered is negligence.

5. **The correct answer is 2.** Obtaining informed consent is part of the physician–patient relationship. If a nurse suspects that a patient does not understand a procedure for which he or she is being asked to give consent or has consented to, the nurse must notify the physician or nursing supervisor.
6. **The correct answer is 4.** If a patient is harmed as a direct result of a nursing student's actions or lack of action, the liability is generally shared by the student, the instructor, the hospital or health care facility, and the university or educational institution.
7. **The correct answer is 4.** A nurse providing emergency assistance at an accident scene would not be covered by an employer's insurance policy because the care given would not be the responsibility of the employer. However, some provinces have passed "Good Samaritan" laws (e.g., Alberta's *Emergency Medical Aid Act*, 1988) that prevent voluntary rescuers from being sued for wrongdoing unless it can be proved that they displayed gross negligence.
8. **The correct answer is 4.** The physician is responsible for directing medical treatment. Nurses are obligated to follow physicians' orders unless they believe the orders are in error, violate hospital policy, or would harm patients.
9. **The correct answer is 3.** Whenever information is requested on a patient by any third parties, including insurance companies or employers, nurses must obtain a signed release by the patient before releasing confidential information.
10. **The correct answer is 4.** Patients can still be identified even if their name is not provided. Individuals can be identified even if a posting is done anonymously or by using a pseudonym. There is a mistaken belief that privacy controls allow the communication to be viewed only by the intended recipient. It is the nurses' role to safeguard all patient information learned in the course of treatment. It is to be shared only on a need-to-know basis with members of the health care team directly involved in the patient's care, when legally required, or where failure to disclose may lead to significant harm.

Chapter 9

1. **The correct answer is 1.** The processes of enculturation and acculturation facilitate cultural learning. Socialization into one's primary culture during childhood is known as *enculturation*.
2. **The correct answer is 2.** In Canada, rather than assimilation, the preferred outcome is multiculturalism, in which immigrants and other people maintain their cultures and different people of diverse cultures interact peacefully within the nation. Canadians believe, as enshrined in the multiculturalism policy, that citizens should be able to retain their unique ethnic cultures and traditions within a Canadian context.
3. **The correct answer is 1.** Cultural awareness is being aware of one's own background, and it involves an in-depth self-examination to recognize biases, prejudices, and assumptions about other people.
4. **The correct answer is 2.** Cultural safety is the outcome of nursing education that enables safe service to be defined by those who receive the service.
5. **The correct answer is 1.** Ethnocentrism is the root of stereotypes, biases, and prejudices against other people who are perceived to be different from the valued group.
6. **The correct answer is 1.** When a person acts on his or her prejudices, discrimination—treating people unfairly on the basis of their group membership—occurs.
7. **The correct answer is 4.** The dominant value orientation in North American society is individualism and self-reliance in achieving and maintaining health. Caring approaches generally promote the patient's independence and ability for self-care.
8. **The correct answer is 3.** Disparities in health outcomes between rich and poor patients illustrate the influence of socioeconomic factors on morbidity and mortality. Social factors such as poverty and lack of access to health resources compromise the health status of poor and unemployed patients.
9. **The correct answer is 3.** Global health focuses on issues that directly or indirectly affect health but that can transcend national boundaries.
10. **The correct answer is 4.** The high value that Western society places on individual autonomy and self-determination may be in direct conflict with the values of diverse groups. Advance directives, informed consent, and consent for hospice are examples of mandates that may violate patients' values.

Chapter 10

1. **The correct answer is 3.** Transformational leadership most fundamentally involves developing relationships to inspire people to be involved in co-creating a vision for change and healthy work environments and positive health outcomes.
2. **The correct answer is 3.** The collaborative practice model is the most inclusive of patient participation in care, and patient centredness is foundational to this model.
3. **The correct answer is 1.** Case management is a care management approach that coordinates and links health care services to patients and their families while streamlining costs and maintaining quality.
4. **The correct answer is 4.** Working in a decentralized structure has the potential for greater collaborative effort, increased staff competency, and a greater sense of professional accomplishment and satisfaction.
5. **The correct answer is 3.** Accountability means being answerable for one's actions. It involves follow-up and reflection on one's decisions to evaluate effectiveness.
6. **The correct answer is 2.** Research shows that the staffing model is an important determinant of a high-quality work life and patient safety.
7. **The correct answer is 1.** It is most important to value the experiences and perspectives of the UCPs and to seek input before setting up educational and support systems.
8. **The correct answer is 1.** First-order priority needs represent an immediate threat to a patient's survival or safety, such as an obstructed airway, loss of consciousness, or an anxiety attack.
9. **The correct answer is 4.** UCPs should not be assigned sole responsibility for patient care. The nurse in charge of patient care decides which activities the UCP can perform independently and which activities must be performed by the nurse and UCP in partnership. UCPs are trained to bathe patients.
10. **The correct answer is 3.** A nurse-sensitive outcome reveals whether interventions are effective, whether patients progress or remain safe, how well standards are being met, and whether changes are necessary. A patient outcome is a measure of the patient's health status as a result of implementing best practice guidelines for preventing falls.

Chapter 11

1. **The correct answer is 1.** An important aspect of critical thinking is reflection: the process of purposefully thinking back or

recalling a situation to discover its purpose or meaning. Nurses should think back on a patient situation, make sense of the experience, and thus gain insight into the meaning of the situation.

2. **The correct answer is 3.** At the basic level of critical thinking, a learner trusts that experts have the right answers for every problem. Thinking is concrete and based on a set of rules or principles. For example, a nurse uses an institution's procedures manual to confirm how to complete a specific procedure.
3. **The correct answer is 2.** The nursing process consists of five steps: assessment, nursing diagnosis, planning, implementation, and evaluation. During the evaluation phase, the nurse evaluates whether the nursing action has been effective.
4. **The correct answer is 3.** The nurse's knowledge base is an important component of critical thinking. It varies according to a nurse's educational experience, including basic nursing education, continuing education courses, and additional university degrees. In addition, it includes the initiative a nurse shows in reading the nursing literature to remain current in nursing science.
5. **The correct answer is 3.** The nurse notices that the intravenous infusion is not functioning correctly and uses his or her knowledge to solve the problem.
6. **The correct answer is 1.** The nurse makes an inference about how well the patient is coping based on the patient's descriptions of how the death of her sister has affected her day-to-day activities (i.e., draws a conclusion based on patterns of behaviour indicative of ineffective coping).
7. **The correct answer is 3.** Based on an assessment and analysis of the physical signs and symptoms, the nurse diagnoses the patient's health status.

Chapter 12

1. **The correct answer is 4.** The other answers relate to diagnosis and intervention, rather than assessment.
2. **The correct answer is 3.** Analyzing and interpreting data, documentation, and sharing of data with other health care providers cannot be done until data is validated and determined accurate.
3. **The correct answer is 4.** Documenting nursing care and reviewing data with other health care providers are part of intervention, not assessment. Making inferences is the step after data clustering.
4. **The correct answers are 1, 3, and 5.** These symptoms are related to the respiratory system and adequate oxygen intake. The others relate to other body systems.
5. **The correct answer is 3.** Diagnosis and treatment of patients' responses describes the entire nursing process; a common nursing language refers to the process of developing nursing diagnoses; identification of a disease refers to evaluation. A nursing diagnosis for an individual patient is the clinical judgement about responses to actual and potential health problems or life processes.
6. **The correct answer is 4.** Data collection, clustering, and interpretation are part of assessment.
7. **The correct answer is 4.** Evaluating nursing care is evaluation, gathering patient information is assessment, and helping nurses focus on their role refers to the entire nursing process.
8. **The correct answer is 4.** A wellness nursing diagnosis describes levels of wellness in an individual, family, or community that can be enhanced. A risk nursing diagnosis describes human responses to health conditions or life processes that may develop in a vulnerable individual. An actual

nursing diagnosis describes responses to health conditions or life processes that exist in an individual, family, or community. A potential nursing diagnosis is one under consideration during data interpretation.

9. **The correct answer is 2.** A wellness nursing diagnosis describes levels of wellness in an individual, family, or community that can be enhanced. A risk nursing diagnosis describes human responses to health conditions or life processes that may develop in a vulnerable individual. An actual nursing diagnosis describes responses to health conditions or life processes that exist in an individual, family, or community. A potential nursing diagnosis is one under consideration during data interpretation.
10. **The correct answer is 1.** Risk factors are evidence considered during assessment; related factors are those contributing to the diagnosis; the complete statement is the nursing diagnosis.
11. **The correct answer is 2.** The patient is the best source of information.
12. **The correct answer is 4.** "*Diarrhea related to intestinal colitis*" refers to a medical condition not responsive to nursing care.
13. **The correct answers are 1 and 2.** The other answers are related factors but do not define the primary diagnosis.

Chapter 13

1. **The correct answers are 2 and 3.** Controlling pain and monitoring vital signs are important direct care priorities for safe and effective care for a patient who has just returned from the recovery room. Family visits and end-of-shift reports are important, but they are not high priorities in the immediate recovery period.
2. **The correct answer is 1.** Maintaining proper drainage of the wound is a high priority for this patient immediately after surgery. The condition of the intravenous dressing, the patient's comfort, and obtaining more intravenous fluids are important, but they do not have the highest priority in this situation.
3. **The correct answers are 1 and 2.** The descriptions "afebrile until discharge" and "without phlebitis by the third postoperative day" reflect the actual condition or state of the patient.
4. **The correct answer is 4.** Rating pain acuity on a scale is the only report of the expected outcome in measurable terms.
5. **The correct answer is 4.** *Collaboration* means that a number of health care providers are involved in care.
6. **The correct answer is 3.** Successful planning requires that you collaborate with the patient and family, consult with other members of the health care team, and review relevant literature. Critical pathways are care plans that detail the essential steps in the care of patients with a specific clinical problem and describe the expected progress of the patient. Concept mapping provides a visual representation showing the connections between many problems.
7. **The correct answer is 2.** Restraining a violent patient is an example of a life-saving measure to protect the patient. Administering analgesics is a physical care technique; it is not a life-saving measure. Stress-reduction therapy is an example of a counselling technique. Teaching the patient how to take his or her pulse is an example of the nursing intervention of teaching.
8. **The correct answer is 1.** Patient safety always comes first.
9. **The correct answer is 2.** A concept map is a diagram of patient problems and interventions that shows their relations to one another. This process promotes critical thinking and helps the nurse to organize complex patient data and achieve a holistic

view of the patient's situation. The purpose is not quality assurance in the health care facility. Multidisciplinary communication is enhanced through the use of critical pathways. Standardized care plans, not concept maps, provide a standardized format for patient problems.

Chapter 14

1. **The correct answer is 3.** Auscultation of lung sounds is an evaluation of the effectiveness of suctioning, which is the nursing intervention being evaluated.
2. **The correct answers are 2 and 4.** Evaluative criteria must relate to the intervention (suctioning) that is intended to clear the patient's airway and lungs to promote normal breathing. Drinking water and reporting abdominal pain are not directly associated with breathing.
3. **The correct answer is 1.** Goals and expected outcomes are objective criteria developed in the plan of care used to judge a patient's response to care. Answers 2 and 4 are both subjective observations of the nurse based on patient feedback.
4. **The correct answer is 3.** Determining adherence to the medical regime is the priority. Antibiotics must be taken routinely and consistently to maintain adequate blood levels. Additional data are required related to the plan of care prior to pursuing other nursing interventions.
5. **The correct answer is 3.** Arranging for five small meals daily reflecting the patient's cultural preferences is an independent intervention and does not require a physician's order. Small frequent feedings palatable to the patient spread throughout the day provide a volume that is not as overwhelming as a full meal. Patients must not be forced to eat all their meals; the portions may be too large for an anorectic patient to ingest. Adding between meal supplements is a dependent intervention and requires a physician's order. The problem is not the number of calories provided at mealtime but the amount of food the patient is able to ingest at any one time.

Chapter 15

1. **The correct answer is 1.** This information about a fellow nursing student is confidential. You cannot share it with classmates or visit him because you learned of his admission accidentally in the course of your work. You have no right to access his EHR because you are not caring for him.
2. **The correct answer is 4.** Enter only objective descriptions of the patient's behaviour, not opinions or judgements. Do not write retaliatory or critical comments about a patient; in a court of law, such comments can be used as evidence of nonprofessional behaviour or poor quality of care.
3. **The correct answer is 3.** Subjective data is what the patient says, and this is often his or her own words in quotation marks.
4. **The correct answer is 4.** Enter only objective descriptions of the patient's behaviour, not opinions or judgements. Do not write retaliatory or critical comments about patient; in a court of law, such comments can be used as evidence of nonprofessional behaviour or poor quality of care.
5. **The correct answer is 1.** Patients frequently request copies of their health records, and they have the right to do so. Each institution has policies for controlling the manner in which records are shared. In most situations, patients are required to give written permission for release of medical information.
6. **The correct answer is 4.** Use complete, concise descriptions of care so that documentation is objective and factual. Avoid using empty phrases such as "well tolerated," which is too generalized and has no meaning.

7. **The correct answer is 3.** Acuity records (also known as workload measurement systems) provide a method of determining the hours of care and staff required for a given group of patients. A patient's acuity level is based on the type and number of nursing interventions required for providing care in a 24-hour period.
8. **The correct answers are as follows:** S = 2, O = 4, A = 3, P = 1. S stands for *subjective*: "The pain increases every time I try to turn on my left side." O stands for *objective*: Left lower abdominal surgical incision, 3 inches in length, closed, sutures intact, no drainage. Pain noted on mild palpation. A stands for *assessment*: Acute pain related to tissue injury from surgical incision. P stands for *plan*: Repositioned patient on right side. Encouraged patient to use patient-controlled analgesia.

Chapter 16

1. **The correct answer is 3.** Changes in the health care system have led to an increased need for high-quality, comparable, aggregated data to support effective decision making—whether decisions at the clinical level, the local or regional level, or the system level. Nurses recognize the value of adopting technology to support evidence-informed professional practice, innovation, and nursing data collection and representation.
2. **The correct answer is 4.** Nursing needs standardized documentation to facilitate aggregation of nursing data, to support comparison and analysis, to enhance communication among nurses, and to improve representation regarding nursing contributions.
3. **The correct answer is 2.** The CNA formally adopted ICNP® as the terminology of choice for professional nursing practice. Standardized nursing terminology using ICNP® is being implemented via the C-HOBIC project. This project will examine nursing sensitive outcomes and compare these measures across various clinical settings. Because all outcomes are coded using ICNP®, this comparison will have a stronger impact and allow for greater analysis.
4. **The correct answer is 1.** Although all nurses must practise using both the Standards of Care (provincial legislation) and the national *Code of Ethics*, all nurses must be aware of both pieces of federal legislation governing the privacy of health information in Canada. The *Privacy Act* and the *Personal Information Protection and Electronic Documents Act* (PIPEDA) prohibit nurses from disclosing personal health information about any patient, with very limited exceptions.
5. **The correct answer is 3.** Nurses can enact the E-Nursing Strategy by engaging in advocating for access and participation and engaging in developing their competencies. Additionally, you should work toward the seven key outcomes as identified by CNA. These include the following:
 - a. Integrating ICT into your practice to achieve good patient outcomes
 - b. Having the required information and knowledge to support your practice
 - c. Facilitating human resources planning
 - d. Support for new models of nursing practice and health services delivery
 - e. Improved connections between nursing groups
 - f. Improved quality of nurses' work environments
 - g. Contributing to the global community of nursing
6. **The correct answer is 1.** Many professional and informal nursing communities are available to foster nurses' engagement in the informatics communities. Canada Health Infoway solicits clinician engagement in support of development of the

pan-Canadian EHR. You can be a voluntary member of any (or several) Standards Collaborative Working Groups (SCWG) and contribute to specific aspects of EHR development. The Canadian Nursing Informatics Association (CNIA) is the national group that all nurses are welcome to join. Additionally, many provinces have special interest groups that are dedicated to nursing informatics. COACH is also another choice for nurses to join a national Canadian group. International opportunities include AMIA, IMIA-SIGNI, and HISA. You may also consider other informal communities such as listservs, wikis, blogs, and other social networks such as Facebook. It is critical, however, to remember that most informal communities are not held to the professional content standards as those of more formal organizations, and content should be considered with caution.

Chapter 17

1. **The correct answer is 4.** Assessment of a patient's ability to communicate includes gathering data about the many contextual factors that influence communication. These include the participants' internal factors and characteristics, the nature of their relationship, the situation prompting communication, the environment, and the sociocultural elements present. Assessing these contextual factors helps you make sound decisions during the communication process.
2. **The correct answer is 3.** Active listening means to be attentive to what the patient is saying both verbally and nonverbally. The acronym *SOLER* represents facilitative skills for attentive listening: *S* (sit facing the patient); *O* (observe an open posture; that is, keep arms and legs uncrossed); *L* (lean toward the patient); *E* (establish and maintain intermittent eye contact); *R* (relax).
3. **The correct answer is 1.** A helping relationship between nurse and patient does not just happen; it is created with care and skill and is built on the patient's trust in the nurse. During the orientation phase of a relationship, the nurse sets the tone for the relationship by adopting a warm, empathic, and caring demeanour. During this phase, the relationship is often superficial, uncertain, and of a social nature. The phase is a period of getting to know each other and establishing trust.
4. **The correct answer is 3.** Interacting with patients who have conditions that impair communication requires sensitivity and creativity. Communication techniques must be adapted to the patient's unique circumstances and sensory, motor, and cognitive needs. The nurse must be patient, ask simple questions, encourage the patient to converse, and allow sufficient time for the patient to understand and respond. Visual cues and communication aids may be useful in communicating with aphasic patients.
5. **The correct answer is 1.** Nurses function in roles that require interaction with multiple members of the health care team. Many elements of the nurse-patient helping relationship are also applied in these collegial relationships, which are focused on accomplishing the work and goals of the clinical setting. It is especially important to involve the patient and family in decisions about the plan of care to determine whether suggested methods are acceptable.
6. **The correct answer is 3.** *Clarifying* means checking whether understanding is accurate, as in restating an unclear or ambiguous message to elicit the sender's meaning. Instead of restating the message, you can also ask the other person to rephrase it, explain further, or give an example of what he or she means.
7. **The correct answer is 4.** Focusing is used to centre on key elements or concepts of a message. If conversation is vague

or rambling, or if patients begin to repeat themselves, focusing is a useful technique.

8. **The correct answer is 2.** Intrapersonal communication, or self-talk, is a powerful communication tool. It strongly influences perceptions, feelings, self-concept, and behaviour and can replace negative thoughts with positive assertions.
9. **The correct answer is 2.** A tip for improved communication with older adults is to stick to one topic at a time.
10. **The correct answer is 2.** In the zones of personal space and touch, the personal zone (45 cm to 1 m) includes nursing activities such as sitting at a patient's bedside and documenting the patient's health history.

Chapter 18

1. **The correct answer is 4.** Touch is one way to offer comfort and communicate concern and support. Touch leads to a connection between nurse and patient. However, touch can convey many messages; it must be used with discretion.
2. **The correct answer is 4.** To know a patient means that the nurse avoids assumptions, focuses on the patient, and engages in a caring relationship with the patient that reveals information and cues that facilitate critical thinking and clinical judgments. Knowing the patient is at the core of the process by which nurses make clinical decisions.
3. **The correct answer is 2.** Enabling is the caring process that helps the new mother's passage through the life transition of birthing. This process is accomplished by preserving dignity, explaining, supporting, focusing, and providing treatment alternatives.
4. **The correct answer is 4.** Spiritual health is achieved when people find a balance between their own life values, goals, and belief systems and those of others. Research has shown a link between spirit, mind, and body. An individual's beliefs and expectations can and do have effects on the person's physical well-being.
5. **The correct answer is 3.** Strategies to enable nurses to demonstrate more caring behaviours include introducing greater flexibility into the work environment structure, rewarding experienced nurse mentors, improving nurse staffing, and providing nurses with autonomy over their practice.
6. **The correct answer is 1.** A nurse demonstrates caring by helping family members become active participants in a patient's care.
7. **The correct answer is 4.** Listening includes not only "taking in" what a patient says but also interpreting and understanding what is said and reflecting that understanding to the person talking.
8. **The correct answer is 3.** Presence involves a person-to-person encounter that conveys closeness and a sense of caring that involves "being there" and "being with" patients.
9. **The correct answer is 1.** Knowing the behaviours that patients perceive as caring helps nurses to understand what patients expect of them as caregivers. Establishing a reassuring presence, recognizing an individual as unique, and being attentive to the patient are recurrent caring behaviours identified by researchers. Each patient has a unique background of experiences, values, and cultural perspectives; however, understanding common behaviours that patients associate with caring will help you learn to express caring in practice.

Chapter 19

1. **The correct answer is 4.** The nurse must think of family as defined by each individual. In other words, the nurse can

think of the family as a set of relationships that the patient identifies as family or as a network of individuals who influence each other's lives, whether the ties actually are biological or legal.

2. **The correct answer is 2.** The blended family is formed when both parents bring children from previous relationships into a new, joint living situation or when children from the current union and children from previous unions are living together.
3. **The correct answer is 4.** The proportion of teenagers giving birth has been declining steadily since the 1980s, probably as a result of increased sexual education, the availability of contraceptives, and the use of abortion.
4. **The correct answer is 4.** The family is the primary social context in which health promotion and disease prevention take place. The family's beliefs, values, and practices also strongly influence health-promoting behaviours of its members.
5. **The correct answer is 3.** Health promotion researchers have focused on the stress-moderating effect of hardiness and resiliency as factors that contribute to long-term health. Family hardiness is the internal strengths and durability of the family unit. Family resiliency is the ability to cope with expected and unexpected stressors.
6. **The correct answer is 2.** When the family as patient is the approach, you focus on the entire family, its processes and relationships (e.g., parenting or family caregiving).
7. **The correct answer is 1.** *Internal structure* refers to the people who are included in the family and how they are connected to each other. Specifically, this question assesses family composition, a subcategory of internal structure. *Family composition* refers to the individual members who form the family. The family composition is not limited to the traditional nuclear family; instead, it may include any of the various family forms.
8. **The correct answer is 3.** In considering family nursing from a relational inquiry perspective, there is an explicit focus on understanding the family in context (sociocultural, geopolitical, and economic contexts).
9. **The correct answer is 3.** Letting be and change, as well as emancipatory action, are two of the assessing and intervening approaches described by Hartrick Doane and Varcoe (2005) in *Family nursing as relational inquiry: Developing health promoting practice* (p. 288).
10. **The correct answer is 4.** *Expressive functioning* refers to the ways in which people communicate. Emotional communication is a subcategory of expressive functioning and encompasses the range and types of feelings that are expressed by the family.
11. **The correct answer is 1.** Circular questions facilitate change by inviting the family to discover their own answers; they help explain a problem.
12. **The correct answer is 3.** In an effective family interview, the nurse can engage a family to assess, explore, and identify strengths and problems. The nurse can also decide to intervene or refer the family to another health care professional.

Chapter 20

1. **The correct answer is 3.** Psychomotor learning involves acquiring skills that require the integration of mental and muscular activity; therefore, teaching a patient to use a walker requires the use of the psychomotor domain. The patient

masters skills by manipulating equipment and practising manual skills.

2. **The correct answer is 2.** If a patient's learning ability is impaired or if distractions are present, the nurse should modify or postpone teaching activities. Any physical condition (e.g., pain, fatigue, or hunger) that depletes energy also impairs the ability to learn. Therefore, the nurse should teach the patient when pain medications are working.
3. **The correct answer is 3.** Readiness to learn is related to the grieving stage. Patients cannot learn when they are unwilling or unable to accept the reality of illness. However, properly timed teaching can help a patient to adjust to illness or disability. When a patient is in denial or disbelief, you should teach in the present tense (e.g., explain what patient needs to know to be discharged).
4. **The correct answer is 4.** As a child matures, intellectual growth moves from concrete to abstract. By developing topics for discussion that require problem solving, the nurse is considering the adolescents' level of development and will engage the students in learning about nutrition.
5. **The correct answer is 3.** Behavioural objectives are measurable and observable and indicate how learning will be evidenced. An objective is more precise when it describes the conditions or timing under which the behaviour occurs (e.g., the patient will perform breast self-examination correctly before the end of the teaching session).
6. **The correct answer is 1.** The telling approach is useful when limited information must be taught (e.g., preparing a patient for an emergency diagnostic procedure).
7. **The correct answer is 3.** Role play helps teach new ideas and attitudes. During role play, patients play themselves or someone else and rehearse a desired behaviour.
8. **The correct answer is 1.** Learning disabilities are disorders that may impair ability to acquire, organize, remember, understand, or apply information. When teaching patients with learning disabilities or other barriers to learning, a recommended technique is to demonstrate procedures such as measuring dosages and then ask for return demonstrations (provides opportunity to clarify instructions and time to review procedures).
9. **The correct answer is 2.** In general, teaching and learning begin when a person identifies a need for knowing or acquiring an ability to do something.
10. **The correct answer is 1.** Demonstrations help teach psychomotor skills such as preparing a syringe. The patient is able to observe a skill before practising it.

Chapter 21

1. **The correct answer is 4.** Growth is the quantitative, or measurable, aspect of an individual's increase in physical measurements. Measurable growth indicators include changes in height, weight, teeth, skeletal structures, and sexual characteristics.
2. **The correct answer is 1.** Moral development is the ability of an individual to distinguish right from wrong and to develop ethical values on which to base his or her actions.
3. **The correct answer is 1.** Organicism is a theoretical focus on the organism itself. According to theories in this tradition, development is a result of biologically driven behaviour and the person's adaptation to the environment.
4. **The correct answer is 1.** Three major categories of factors influence human growth and development: genetics,

environment, and the interaction between these two. The family is an example of an environmental factor. Family influences through its values, beliefs, customs, and specific patterns of interaction and communication.

5. **The correct answer is 4.** Psychiatrist Robert Havighurst believed his findings described a sequential process that takes place between the internal life (personality) of adults and their outer world (culture, lifestyle).
6. **The correct answer is 4.** The zone of proximal development, described by Vygotsky, is the difference between a child's current developmental achievement and a child's capabilities, given their physical and emotional maturation level. For example, a 12-month-old child may be walking by holding on to furniture but be developmentally able to walk independently. A sensitive caregiver could help the child achieve independent walking by encouraging activities that help the child gain confidence to walk alone.
7. **The correct answer is 1.** During formal operations, the individual's thinking moves to abstract and theoretical subjects. Thinking can venture into such subjects as achieving world peace, finding justice, and seeking meaning in life. Adolescents can organize their thoughts in their minds. New cognitive powers allow the adolescent to achieve more far-reaching problem solving.
8. **The correct answer is 2.** The microsystem consists of the immediate settings, activities, and personal relationships of the individual. Examples of microsystems are family, classroom, workplace, or recreation group.
9. **The correct answer is 3.** According to Keating and Hertzman's (1999) population health approach, human development is a population phenomenon. They referred to the strong association between the health of a population, developmental outcomes, and the social and economic forces affecting the larger society. Therefore, improving community housing would be an attempt to improve the health of the population.
10. **The correct answer is 4.** According to resilience theory, protective processes shield people from adversity and include social supports, such as high-quality day care.

Chapter 22

1. **The correct answer is 1.** Maternal risk factors associated with preterm labour include physiological stresses such as renal and cardiovascular disease, diabetes mellitus, and uterine and cervical abnormalities.
2. **The correct answer is 2.** Fathers are a major source of breastfeeding support and their knowledge and encouragement of breastfeeding can influence initiation and duration (Rempel & Rempel, 2010).
3. **The correct answer is 2.** Healthy infants begin their routine immunization schedule at two months of age so that they may be protected against infectious diseases as early as possible.
4. **The correct answer is 4.** According to Piaget (1952), during the preoperational thought stage of cognitive development, toddlers recognize that they are separate beings from their mothers, but they are unable to assume another person's viewpoint. They use symbols to represent objects, places, and people. This function is demonstrated when children imitate the behaviour of another person that they viewed earlier (e.g., pretend to shave like their daddy).
5. **The correct answer is 3.** The play of preschool children becomes more social after the third birthday as it shifts from

parallel to associative play. Most three-year-old children are able to play with one other child in a cooperative manner in which they make something or play designated roles such as mother and baby. By the age of four years, children play in groups of two or three, and by five years, the group has a temporary leader for each activity.

6. **The correct answer is 2.** Preschoolers average 12 hours of sleep a night and take infrequent naps.
7. **The correct answer is 4.** The nurse is legally required to report all cases of suspected child abuse or neglect to authorities.
8. **The correct answer is 1.** Obesity has become the most common nutritional disturbance in childhood. You can help children avoid this problem by teaching about and encouraging a balanced healthy diet, promoting physical exercise and limiting inactivity, and promoting a healthy body image.
9. **The correct answer is 3.** Good communication skills are critical for overcoming peer pressure and unhealthy behaviours. The following are some hints for communicating with adolescents: do not avoid discussing sensitive issues, ask open-ended questions, look for the meaning behind their words or actions, be alert to clues to their emotional state, and involve other individuals and resources when necessary.
10. **The correct answer is 3.** Injuries, including self-inflicted injuries and injuries caused by motor vehicle accidents and poisoning, are the leading cause of death in adolescents.

Chapter 23

1. **The correct answer is 2.** Most young adults have completed physical growth by the age of 20 years.
2. **The correct answer is 1.** Your role in health promotion is to identify lifestyle risk factors and provide education and support to reduce unhealthy behaviours.
3. **The correct answer is 4.** When determining the amount of information the individual needs to make decisions about the prescribed course of therapy, you should consider factors that may affect the individual's compliance with the regimen, including educational level, socioeconomic factors, motivation, and desire to learn.
4. **The correct answer is 4.** A common physiological change in the second trimester is quickening, which is the sensation of fetal movements as experienced by the pregnant woman.
5. **The correct answer is 2.** Accidents are the leading causes of accidental injury for young adults.
6. **The correct answer is 2.** Close friends and associates of the single young adult may also be viewed as the individual's "family."
7. **The correct answer is 3.** A family history of a disease may put a young adult at risk for developing that disease in the middle or older adult years. For example, if a young man's father and paternal grandfather had myocardial infarctions (heart attacks) in their 50s, his risk for a future myocardial infarction is increased.
8. **The correct answer is 3.** In the middle adult years, as children depart from the household, the family enters the postparental family stage. Time and financial demands on the parents decrease, and the couple faces the task of redefining their relationship.
9. **The correct answer is 3.** Health teaching and health counselling are often directed at improving health habits.
10. **The correct answer is 3.** The physiological response to stress can be avoided. You use relaxation techniques, imagery, and biofeedback to recondition the patient's response to stress.

Chapter 24

1. **The correct answer is 4.** Two factors contribute to the projected increase in the number of older adults: the aging of the baby-boom generation and the growth of the population segment older than 85 years. The baby boomers are the adults born between 1946 and 1964.
2. **The correct answer is 3.** Various theorists have attempted to describe the complex biopsychosocial process of aging. Although many theories have been developed, no single universally accepted theory predicts and explains the complexities of the aging process.
3. **The correct answer is 3.** The three common conditions affecting cognition are delirium, dementia, and depression. The nurse may find that distinguishing among these three conditions is challenging but essential.
4. **The correct answer is 2.** Sexuality is increasingly recognized as an important factor in the lives of older adults. All older adults, whether healthy or frail, need to express sexual feelings. Sexuality involves love, warmth, sharing, and touching, not just the act of intercourse.
5. **The correct answer is 1.** The libido does not decrease in older adults, although frequency of sexual activity may decline. An older woman who does not understand physical changes affecting sexual activity may be concerned that her sex life is nearly over. The older man may feel the same when he discovers a change in the firmness of his erection, a decreased need for ejaculation with each orgasm, or a longer recovery period between episodes of intercourse.
6. **The correct answer is 3.** Presbyopia (the gradual decline in the ability to focus on near objects) is common in older adults.
7. **The correct answer is 1.** Presbycusis, common in older adults, is a decrease in the ability to hear high-pitched sounds and sibilant consonants such as "s," "sh," and "ch."
8. **The correct answer is 1.** Taste buds atrophy and lose sensitivity. Older adults are less able to discern among salty, sweet, sour, and bitter tastes.
9. **The correct answer is 4.** The anteroposterior diameter of the thorax increases. The incidence of osteoporosis is increased in older adults; vertebral changes caused by osteoporosis lead to dorsal kyphosis, the curvature of the thoracic spine sometimes called "dowager's hump."
10. **The correct answer is 1.** Frontotemporal dementia has an insidious onset and progresses slowly. Early symptoms include poor hygiene, lack of social tact, hyperorality, and sexual disinhibition. Incontinence is an early symptom in frontotemporal dementia, whereas it is a late symptom in the more common Alzheimer's disease.

Chapter 25

1. **The correct answer is 2.** Self-concept is how a person thinks about himself or herself. It is a subjective sense of the self and a complex mixture of unconscious and conscious thoughts, attitudes, and perceptions. Mastectomy is a surgical procedure that alters the appearance and function of the body. Although the changes may not be apparent to other people when the individual is dressed, these bodily changes have a significant impact on the individual.
2. **The correct answer is 2.** One of the self-concept developmental tasks of one- to three-year-olds is developing self through modelling, imitation, and socialization.
3. **The correct answer is 4.** Identity involves the internal sense of individuality, wholeness, and consistency of a person over time and in various circumstances.

4. **The correct answer is 3.** Body image depends only partly on the reality of the body. Body image involves attitudes related to the body, including physical appearance, structure, or function. Feelings about body image include those related to sexuality, femininity and masculinity, youthfulness, health, and vitality. These mental images are not always consistent with a person's actual physical structure or appearance.
5. **The correct answer is 1.** Through the process of reinforcement-extinction, certain behaviours become common or are avoided, depending on whether they are approved and reinforced or are discouraged and punished.
6. **The correct answer is 4.** Through the process of identification, an individual internalizes the beliefs, behaviour, and values of role models into a personal, unique expression of self.
7. **The correct answer is 3.** An individual's identity is affected by stressors throughout life but is particularly vulnerable during adolescence, a time characterized by many changes.
8. **The correct answer is 1.** Identity confusion results when a person does not maintain a clear, consistent, and continuous consciousness of personal identity.
9. **The correct answer is 3.** By asking patients how they feel about themselves, the nurse is seeking information about their self-esteem.
10. **The correct answer is 1.** Increasing the patient's self-awareness is achieved through establishing a trusting nurse-patient relationship that allows the patient to openly explore thoughts and feelings.

Chapter 26

1. **The correct answer is 3.** *Gender identity* refers to the degree to which a person identifies as male, female, or some combination. It begins in early childhood as the child becomes aware of the differences of the sexes and perceives that he or she is male or female.
2. **The correct answer is 2.** *Sexual health* means that a person has freedom from physical and psychological impairment, awareness of and positive attitudes toward sexual functioning, and accurate knowledge about sexuality.
3. **The correct answer is 4.** Sexual dysfunction is the absence of complete sexual functioning.
4. **The correct answer is 1.** A major problem in dealing with STIs is that symptoms are absent or go unnoticed. Finding and treating the people who have them can be difficult. Some people who are infected may not even know that they are.
5. **The correct answer is 2.** The most common bacterial STI is genital chlamydia. (HIV infection and AIDS are viral STIs.) A chlamydial infection may cause an abnormal genital discharge and burning with urination. There are many serious complications of genital chlamydia in women, including chronic pelvic pain, infertility, and ectopic pregnancy.
6. **The correct answer is 1.** Contraceptive methods that require a health care provider's intervention include hormonal contraception, intrauterine devices (IUDs), the diaphragm, the vaginal contraceptive ring, the cervical cap, and surgical procedures (vasectomy and tubal ligation).
7. **The correct answer is 2.** Effectiveness rates are as follows: for birth control pills, 98% to 99%; for the contraceptive sponge, 80% to 91%; for vaginal spermicides, 78% to 90%; and for the female condom, 79% to 85%.
8. **The correct answer is 2.** The most valuable tool that you can use when providing care in areas of sexuality is effective, nonjudgemental communication. A perceptive and educated approach to talking about sexuality can offer the support that

many patients require. Effective communication about sexuality requires caring, sensitivity, tact, compassion, the use of appropriate language, and nondiscriminatory attitudes.

9. **The correct answer is 3.** When caring for older adults, you may adjust your assessment approach. When gathering a sexual history from an older adult, it is important to keep in mind that the patient may have difficulty discussing intimate details with health care providers. You are responsible for helping maintain the sexuality of older adults by offering the opportunity to discuss any concerns. Often, asking questions on the topic of sexuality in a comfortable, relaxed manner facilitates older adults' discussion of their sexual needs.
10. **The correct answer is 1.** A useful framework to guide planning is the PLISSIT model developed by Annon (1976). P stands for "permission giving." During assessment, you can bring up the topic of sexuality and can give the individual permission to talk about sexual concerns. LI stands for "limited information," which is basic information regarding sexuality and sexual functioning. SS stands for "specific suggestions," whereby you provide specific suggestions regarding a sexual concern or issue. If you are not equipped to address a particular concern, you should refer the patient to another health care provider. IT stands for "intensive therapy." At this level of intervention, your role is to refer the patient to a qualified practitioner, such as a social worker or a sex counsellor, for individualized therapy.

Chapter 27

1. **The correct answer is 3.** Caring for a patient's spiritual needs means caring for the whole person, accepting his or her beliefs and experiences, and helping the patient with issues surrounding meaning and hope. Praying for the patient and calling for a religious leader may be appropriate in some situations but those situations must be directed by the patient and considered carefully.
2. **The correct answer is 2.** Atheists do not believe in the existence of God. Agnostics believe that any ultimate reality is unknown. This does not mean that spirituality is not an important concept for the atheist or agnostic. Atheists search for meaning in life through their work and their relationships with other individuals. However, it is important not to assume that spirituality would be an acceptable term to describe this search for meaning because of its long relationship to religion.
3. **The correct answer is 4.** Research has indicated that providing structure and support for patients' rituals and practices is an important intervention. This is not always assigned a high priority by nurses because they may not see it as an important part of modern medicine. However, it is important to note that it is often a critical part of a patient's personal medicine.
4. **The correct answer is 1.** Presence is an important way of being with patients that facilitates spiritual care.
5. **The correct answer is 2.** Those from the Hindu religion may observe important days of fasting. It is important to understand and facilitate that practice.
6. **The correct answer is 4.** Reviews of spirituality in the literature have indicated that it is associated with meaning, purpose, hope, and connectedness. Although spirituality is closely affiliated with religion in some individuals, individuals on a spiritual journey may or may not describe themselves as religious.
7. **The correct answer is 1.** Research has indicated that patients prefer support for their own spiritual practices rather than the more intimate interventions that may be implemented by nurses. Patients also want nurses to know about their spiritual practices and appreciate the little extras that nurses do to make them feel cared for.
8. **The correct answer is 4.** Values are an important part of religion and spirituality. Times of grief and suffering may lead to changes in those values.
9. **The correct answer is 4.** Spiritual assessment requires a great deal of sensitivity and should be adapted to the circumstances.
10. **The correct answer is 2.** Relational practice is foundational for all of nursing care and helps to create an environment for sensitive spiritual care.

Chapter 28

1. **The correct answer is 1.** An actual loss is any loss of a person or object that can no longer be felt, heard, known, or experienced by the individual. Lost objects that have been valued by a patient include any possession that is worn out, misplaced, stolen, or ruined.
2. **The correct answer is 2.** A perceived loss is any loss that is uniquely defined by the grieving patient. It may be less obvious to others.
3. **The correct answer is 3.** Situational loss includes any sudden, unpredictable external event.
4. **The correct answer is 4.** During Bowlby's phase of disorganization and despair, an individual may constantly examine how and why the loss occurred.
5. **The correct answer is 4.** During Kübler-Ross's stage of depression, the person finally realizes the full impact and significance of the loss and may feel overwhelmingly lonely and withdraw from interpersonal interaction.
6. **The correct answer is 2.** Worden's task 3 is to adjust to the environment in which the deceased is missing. According to Worden, a person does not realize the full impact of a loss for at least three months. At this point, many friends and associates make less frequent contact, and the person is left to ponder the full impact of loneliness.
7. **The correct answer is 3.** Loneliness and problems associated with completing the tasks of daily living are two of the most common and difficult adjustments for older bereaved spouses.
8. **The correct answer is 4.** Expression of hopefulness is an expected outcome for patients experiencing a loss.
9. **The correct answer is 2.** For transplantation of organs, ventilatory and circulatory support must be maintained until the organs are harvested. The family must clearly understand that the patient is "brain dead" and that the equipment (i.e., ventilator and vasopressor medications) is not keeping the patient alive but keeping the physical body in a state so that the organs will not be damaged before being harvested.
10. **The correct answer is 3.** Palliative care allows patients to make more informed choices, achieve better alleviation of symptoms, and have more opportunity to manage unfinished business.

Chapter 29

1. **The correct answer is 1.** The medulla oblongata controls vital functions necessary for survival, including heart rate, blood pressure, and respiration.
2. **The correct answer is 4.** The general adaptation syndrome is a three-stage reaction to stress. During the alarm reaction, rising hormone levels result in increases in blood volume, blood glucose levels, epinephrine and norepinephrine levels, heart

rate, blood flow to muscles, oxygen intake, and mental alertness.

3. **The correct answer is 3.** Post-traumatic stress disorder (PTSD) can develop after a traumatic injury or event.
4. **The correct answer is 3.** Situational stress can arise from the person's current circumstances, such as moving, changing jobs, and adjusting to a chronic illness or condition.
5. **The correct answer is 2.** The nurse uses the interview to determine the patient's perception of the stressor by asking the patient what is of the most concern at this time.
6. **The correct answer is 4.** Three primary modes of coping with stress are to decrease exposure to stress-producing situations, increase resistance to stress by increasing action-oriented coping strategies, and learn skills that reduce physiological response to stress. A support group can provide information about a wide range of coping strategies, guidance about reducing exposure to stressful situations, and shared training sessions on techniques to reduce physiological responsiveness.
7. **The correct answer is 2.** In the presence of anxiety-provoking thoughts and events, a common physiological symptom is muscle tension. Physiological tension will be diminished through a systematic approach of relaxing major muscle groups.
8. **The correct answer is 4.** Rapid changes in health care technology, diversity in the workforce, organizational restructuring, and changing work systems can place stress on nurses.
9. **The correct answer is 1.** A crisis creates a turning point in a person's life because it changes the direction of a person's life in some way. The precipitating event usually occurs from one to two weeks before the individual seeks help, but it may have occurred within the past 24 hours. In general, a crisis is resolved in some way within approximately six weeks.

Chapter 30

1. **The correct answer is 3.** Bradycardia is a slow heart rate, slower than 60 beats per minute in adults. Bradypnea is an abnormally slow rate of breathing, slower than 12 breaths per minute.
2. **The correct answer is 1.** An inefficient contraction of the heart that fails to transmit a pulse wave to the peripheral pulse site creates a pulse deficit. To assess a pulse deficit, the nurse and a colleague assess radial and apical rates simultaneously and then compare rates. The difference between the apical and radial pulse rates is the pulse deficit.
3. **The correct answer is 1.** The normal temperature range gradually drops as individuals approach older adulthood. Older adults have a narrower range of body temperatures than do younger adults. Oral temperatures of 35°C are not unusual for older adults in cold weather. However, the average body temperature of older adults is approximately 36°C.
4. **The correct answer is 2.** Blood pressure measurements are not accurate unless the blood pressure cuff is the correct size. If the cuff is too small, it tends to become loose if inflated; this results in false high readings.
5. **The correct answer is 3.** Apnea is the cessation of breathing. It may occur during sleep, in which it is most often caused by obstruction from relaxed tissues. With respiratory effort, it can be followed by normal breathing.
6. **The correct answer is 3.** Patients should never alter the prescribed antihypertensive medication unless otherwise directed by their ordering health care provider as this could lead to unstable BP management. It is important, though, to teach patients about measures they can take to modify their diet (e.g., sodium and fat reduction, alcohol limitations) and

reduce stress. Additionally, many will require instruction on how to measure BP at home, acceptable values, and when to notify health care providers when values are out of range.

7. **The correct answer is 1.** The blood pressure measurements indicate that the patient has orthostatic hypotension. If orthostatic hypotension is assessed, the patient is assisted to a supine position, and the physician or nurse in charge is then notified. While obtaining orthostatic measurements, the nurse observes for other symptoms of hypotension, such as fainting, weakness, or light-headedness.
8. **The correct answer is 2.** If the nurse detects an abnormal rate while palpating a radial pulse, the next step is to assess the apical rate. The apical rate requires auscultation of heart sounds, which provides a more accurate assessment of cardiac contraction.
9. **The correct answer is 1.** Conduction is the transfer of heat from one object to another with direct contact. Heat is conducted through contact with solids, liquids, and gases. When the warm skin touches a cooler object, heat is lost. Conduction normally accounts for a small amount of heat loss. The nurse increases conductive heat loss when bathing a patient with a cool cloth.
10. **The correct answer is 3.** Diseases causing poor oxygenation, such as asthma or chronic obstructive pulmonary disease (COPD), cause an increase in pulse rate.
11. **The correct answer is 3.** A reduction in respiratory rate and depth will not reflect inaccuracies in measurement as this is the purpose of obtaining oxygen saturations. Reduced circulation to extremities due to disease or hypothermia can cause poor transmittal of information to the oximeters probe. Bright light near the measuring probe can cause inaccurate readings as the oximeter obtains saturation readings through the measurement of light through a photo detector and if there is too much ambient light, results could be influenced. Covering the measuring site with a blanket while taking the reading would help to improve readings.
12. **The correct answer is 1.** The basic techniques of inspection, palpation, and auscultation are used to measure vital signs.

Chapter 31

1. **The correct answer is 1.** Rationale: Appearance and behaviour are assessed during a general survey. Measurement of vital signs and observing specific body systems are separate components of the physical assessment process and are usually done after the general survey. Conducting a detailed health history usually occurs before the physical examination. Data from the health history guides the physical exam.
2. **The correct answer is 3.** Compared to the fingertips, palmar surface, and base of the hands, the dorsal surface has comparatively less superficial blood supply and less muscle mass. Therefore it remains slightly cooler to touch and so offers a better contrast by which to detect warm skin during physical examination.
3. **The correct answer is 4.** The pads of the index and middle fingertips are the most sensitive part of the hand so the most suitable for palpating lymph nodes, which are usually small and discrete. If deep palpation or excessive pressure is applied, you will miss small nodes and may destroy palpable nodes. Bimanual technique would imply using both hands to examine the same lymph nodes at the same time, whereas when both hands are used to examine lymph nodes (e.g., in the neck), each hand works independently to examine and compare the nodes on opposite sides of the neck.

4. **The correct answer is 3.** Skin lesions that are symmetrical, uniform in colour, and less than 6 mm in diameter are less likely to be dangerous. The warning signs of dangerous skin lesions include asymmetry or irregular borders, more than one colour, changes in size or colour, bleeding, and tenderness. Refer to Table 31-8 to review the descriptions of skin lesions.
5. **The correct answer is 3.** A side-to-side auscultation pattern allows the nurse to compare each lung and determine if adventitious sounds are bilateral or unilateral, which is an important assessment finding that points to potential specific causes of abnormal findings (e.g., COPD would cause bilateral adventitious sounds; pneumothorax would cause unilateral adventitious sounds).
6. **The correct answer is 3.** Rhonchi are loud, low-pitched, rumbling, coarse sounds heard most often during inspiration or expiration. Refer to Table 31-21 for review of each of the breath sounds heard on auscultation.
7. **The correct answer is 3.** S₂ correlates with the closure of the aortic and pulmonic valves. S₁ correlates with the closure of the mitral and tricuspid valves. Refer to Figure 31-36 to review the phases of the cardiac cycle.
8. **The correct answer is 4.** The dorsalis pedis is the pulse point on the dorsal surface of the foot (refer to Figure 31-53). The pulse palpated in the posterior aspect of the knee is the popliteal pulse (refer to Figure 31-52), whereas the pulse palpated in the groove behind the medial malleolus is the posterior tibial pulse (refer to Figure 31-54). There is no pulse point over the lateral malleolus.
9. **The correct answer is 4.** Ipsilateral means on the same side of the body as the breast being examined. The supine position allows the breast tissue to flatten evenly against the chest wall. The patient raises her hand and places it behind the neck to further stretch and position breast tissue evenly (refer to Figure 31-60, A). Place a small pillow or towel under the patient's shoulder blade to further position breast tissue.
10. **The correct answer is 2, 4, 3, 1.** Inspection, auscultation, percussion, palpation. The order of an abdominal examination differs slightly from assessments in the other systems. Begin with inspection and follow with auscultation. By using auscultation before palpation, there is less chance of altering the frequency and character of bowel sounds.
11. **The correct answer is 2.** A painless, pea-sized lump is an abnormal finding that needs to be reported to the patient's health care provider. The testes are normally round, movable, and smooth, rather than lumpy. The nurse should advise the patient to do a testicular self-examination monthly. The best time is after a warm bath or shower when the scrotal skin is less thick.
12. **The correct answer is 4.** Adduction refers to movement of a limb toward the midline of the body, abduction is away from the midline. Refer to Table 31-32 for descriptions of normal range of motion for joints.
13. **The correct answer is 4.** Interpreting abstract ideas or concepts reflects the capacity for abstract thinking. For an individual to explain common phrases such as "A stitch in time saves nine" or "Don't count your chickens before they're hatched" requires a higher level of intellectual function. Note whether the patient's explanations are relevant and concrete. The patient with altered mental status will probably interpret the phrase literally or merely rephrase the words. Judgement requires a comparison and evaluation of facts and ideas to understand their relationships and to form appropriate conclusions. Asking how much the patient knows about his or

her illness or the reason for seeking health care can assess a patient's knowledge. Association involves finding similarities or associations between concepts.

14. **The correct answer is 4.** Cranial nerve XI is the spinal accessory nerve. It provides motor function to move the head and shoulders. Refer to Table 31-37 to review cranial nerve function and assessment.
15. **The correct answer is 3.** Elevated blood pressure is not a normal physical finding in any patient, whereas each of the three other choices is a common variation of normal findings based on the individuals' biocultural background.
16. **The correct answer is 2.** Lithotomy position requires flexion of about 90 degrees and abduction at the hip, which may place stress on the hip joint. The other three choices require only mild flexion at the hip joint and adduction rather than abduction, therefore stress on the joint is minimal.

Chapter 32

1. **The correct answer is 1.** If an infection can be transmitted from one person to another either directly or indirectly, it is a communicable (infectious, contagious) disease.
2. **The correct answer is 1.** Hepatitis A is transmitted by direct and indirect contact. Hepatitis A can be transmitted person to person by the fecal-oral route. It can also be transmitted indirectly via contaminated water or infected food handlers.
3. **The correct answer is 4.** The interval when a patient manifests signs and symptoms specific to the type of infection (e.g., common cold manifested by sore throat, sinus congestion, or rhinitis) is the illness stage.
4. **The correct answer is 2.** Hand hygiene is the most important and most basic technique in preventing the transmission of infections. Hand hygiene includes using an instant alcohol hand antiseptic before and after providing patient care, hand-washing with soap and water when hands are visibly soiled, and performing a surgical scrub when necessary. The components of good handwashing are using an adequate amount of soap, rubbing the hands together to lather the soap and create friction, and rinsing under a stream of water.
5. **The correct answer is 2.** Washing times of at least 15 seconds are needed to remove most transient microorganisms from the skin. If the hands are visibly soiled, more time may be needed.
6. **The correct answer is 2.** Before isolation measures are instituted, the patient must understand the nature of the disease or condition, the purposes of isolation, and the steps for carrying out specific precautions. You also take measures to improve the patient's sensory stimulation during isolation.
7. **The correct answer is 4.** Gowns or cover-ups protect health care workers and visitors from coming in contact with infected material, blood, or body fluid, or contaminated surfaces or objects in the environment.
8. **The correct answer is 2.** Gloves should be removed promptly after use and hand hygiene performed before touching non-contaminated items and environmental surfaces, before moving from a contaminated body site to a clean body site on the same patient, and before going to another patient.
9. **The correct answer is 2.** Contact precautions are needed when standard precautions or routine practices are not sufficient to prevent transmission. *C. difficile* spores have a high potential for environmental contamination and can be spread to other patients via health care workers' hands and contaminated equipment.
10. **The correct answer is 1.** When you are doing a surgical scrub, you must keep your hands above your elbows.

Chapter 33

1. **The correct answer is 1.** Right to refuse has been added to the five rights of medication administration. It is important to remember that a patient has the right to refuse a medication. Ensuring that patients know that they have the right to refuse is important to maintain person-centred care. Patients need to be informed that they have this right, but at the same time, they also need to be fully informed about the potential consequences of their refusal.
2. **The correct answer is 2.** A medication order is required for any medication to be administered. To protect patient safety, you should ensure the medication order contains all the elements (e.g., medication name, dose, route). If the medication order is incomplete, you should inform the prescriber and ensure completeness before carrying out the medication order. Incomplete transcriptions are a source of medication errors.
3. **The correct answer is 1.** The primary contraindications to administering oral medications include the presence of gastrointestinal alterations, the inability of a patient to swallow foods or fluids, the risk of aspiration in patients with impaired ability to swallow, and the use of gastric suction.
4. **The correct answer is 1.** A medication error is any event that could cause or lead to a patient either receiving inappropriate medication therapy or failing to receive appropriate medication therapy. Most medication errors occur when you fail to follow routine procedures, such as checking dose calculations, deciphering illegible handwriting, and recording the names of or administering medications with which you are unfamiliar.
5. **The correct answer is 4.** Apply the following formula for solid dose forms of medications: $\text{Dose ordered} / \text{Dose on hand} \times \text{Amount on hand} = \text{Amount to administer}$
 $500 \text{ mg} / 250 \text{ mg} \times 1 \text{ tablet} = 2 \text{ tablets}$
 Therefore, if the physician orders 500 mg orally (PO) of Keflex and the medication is only available in tablets containing 250 mg, 2 tablets should be administered.
6. **The correct answer is 3.** Subcutaneous injections involve placing medications into the loose connective tissue under the dermis. Because subcutaneous tissue is not as richly supplied with blood as the muscles, absorption is commonly slower than intramuscular injections.
7. **The correct answer is 1.** You are responsible for following legal provisions when administering controlled substances (drugs that alter the mind or behaviour patterns), which can be dispensed only with a prescription. Violations of the *Narcotic Control Act* are punishable by fines, imprisonment, and loss of nurse licensure or registration.
8. **The correct answer is 2.** Pharmacokinetics is the study of how medications enter the body, reach their site of action, are metabolized, and exit the body. Use your knowledge of pharmacokinetics when timing medication administration, judging the patient's risk for alterations in medication action, and observing the patient's response.
9. **The correct answer is 4.** Official publications, such as the *British Pharmacopoeia* and the *Canadian Formulary*, set standards for drug strength, quality, purity, packaging, safety, labelling, and dosage form. Physicians, nurses, and pharmacists depend on these standards to ensure that patients receive pure drugs in safe and effective dosages.
10. **The correct answer is 1.** Administration of the *Food and Drugs Act* and the *Controlled Drugs and Substances Act* is carried out by the Health Protection Branch (HPB) of the federal government. Before a new drug can be marketed in Canada, an

application for approval must be made to the HPB. After intensive testing, the HPB reviews the application. When sufficient information has been accumulated to ensure its safety, the drug is released for general use.

Chapter 34

1. **The correct answer is 3.** Despite the success of allopathic medicine (traditional Western medicine), many health conditions are difficult to treat: for example, arthritis, chronic back pain, gastrointestinal problems, allergies, headaches, and insomnia. Many patients with these health conditions choose to explore alternative methods to relieve their symptoms.
2. **The correct answer is 4.** Many complementary therapies, such as acupuncture, require diagnostic and therapeutic methods specific to their field, whereas other complementary therapies, such as guided imagery and breathwork, are, in general, easily learned and applied.
3. **The correct answer is 1.** One study reported that 74% of Canadians had used some form of CAM in their lifetimes with the purpose of preventing illness and or maintaining wellness.
4. **The correct answer is 1.** Holistic nursing regards and treats the mind, body, and spirit of the patient. Nurses can use holistic interventions such as relaxation therapy, guided imagery, music therapy, simple touch, massage, and prayer. Such interventions affect the whole person (mind-body-spirit) and are economical, noninvasive, nonpharmacological complements to traditional medical care.
5. **The correct answer is 1.** Some complementary and alternative medicine therapies and techniques use natural processes, such as breathing, concentration, and simple touch, to help patients feel better and cope with chronic conditions. You can learn these techniques with minimum preparation, and many of these procedures can be used with patients as part of your independent nursing practice (Dossey et al., 2013). Adequate assessment and the patient's permission are prerequisites for implementing a complementary medicine therapy.
6. **The correct answer is 1.** According to one of the principles of complementary and alternative medicine therapies, the individual must be actively involved in the treatment. Patients achieve better responses if they practise the techniques or exercises daily. The patient must commit to implementing and maintaining the therapy until a desired outcome is achieved.
7. **The correct answer is 3.** St. John's wort is effective as a mild antidepressant and sedative.
8. **The correct answer is 1.** Meditation can augment the effects of certain drugs. For example, individuals taking antihypertensive, antidepressant, or anti-anxiety medications should be monitored. Prolonged practice of meditation techniques may, in some cases, lead to the reduced need for certain medications, and some doses of medications may need to be adjusted.
9. **The correct answer is 2.** Biofeedback techniques are frequently used in addition to relaxation interventions to assist individuals in learning how to control specific autonomic nervous system responses.
10. **The correct answer is 2.** Therapeutic touch is a training-specific therapy that was developed in the 1970s by a nurse, Dr. Dolores Krieger. Although the philosophical and religious assumptions of therapeutic touch differ from those of other Eastern healing modalities, both practices involve trained practitioners who attempt to direct their own balanced energies in an intentional and motivated manner toward the patient.

Chapter 35

1. **The correct answer is 3.** To reduce the risk of injury to you and the patient, you must understand and practise techniques for safe lifting, positioning, and transfer. This includes knowledge of the actions of various muscle groups, understanding the factors involved in the coordination of body movement, and familiarity with the integrated functioning of the skeletal, muscular, and nervous systems, as well as the correct use of lifting and positioning equipment.
2. **The correct answer is 1.** Proprioception is the awareness of the position of the body and its parts. Proprioception is monitored by proprioceptors located on nerve endings in muscles, tendons, and joints. Posture is regulated by the nervous system and requires coordination of proprioception and balance.
3. **The correct answer is 3.** The Canadian Society of Exercise Physiology's 2011 Canadian Physical Activity Guidelines recommend adults get 150 minutes of moderate to vigorous intensity aerobic physical activity per week.
4. **The correct answer is 1.** Older adults may walk more slowly and appear less coordinated. They also may take smaller steps, keeping their feet closer together, which decreases their base of support. Thus, body balance may become unstable, and they are at greater risk for falls and injuries.
5. **The correct answer is 4.** Patients are more open to developing an exercise program if they are at the stage of being ready to change their behaviour. Information on the benefits of regular exercise may be helpful to the patient who has not yet reached the stage of being ready to act.
6. **The correct answer is 2.** It is increasingly clear that children are becoming less active, resulting in an increase in childhood obesity. Children and adolescents spend a great deal of their time in school, yet most Canadian children currently do not receive the recommended five periods of physical activity per week. Physical education has become an optional subject in most secondary schools, and only 18 percent of Canadian teenagers are accumulating enough daily activity to meet the international guidelines for optimal growth and development.
7. **The correct answer is 4.** The nurse has a responsibility to use patient handling equipment that he or she has been trained to use. The nurse must not put himself or herself or allow colleagues or patients to be put at risk of injury. The nurse has an obligation to report any unsafe situations to a supervisor and follow up to ensure resolution for the safety of all.

Chapter 36

1. **The correct answer is 2.** In Canada, accidental injuries are the leading cause of death for individuals between the ages of 1 and 34 years.
2. **The correct answer is 2.** Adolescents are at greatest risk for injury from motor vehicle accidents, suicide, and substance abuse.
3. **The correct answer is 1.** Advancing age and the concurrent physiological changes in vision, hearing, mobility, reflexes, circulation, and the ability to make quick judgements predispose older adults to falls.
4. **The correct answer is 2.** WHMIS consists of three main elements: worker education programs, cautionary labelling of products, and the provision of MSDSs.
5. **The correct answer is 2.** Procedure-related accidents occur during therapy. They include medication and fluid administration errors, the improper application of external devices, and accidents related to the improper performance of procedures (e.g., improper Foley catheter insertion).

6. **The correct answer is 4.** A patient who cannot weight-bear needs to be moved using a mechanical lift, to protect the nurse from injury and in turn maintain the safety of the patient.
7. **The correct answer is 3.** Restraints are *not* considered a long-term intervention. Restraints are used only after other alternatives have been tried, and the least-restrictive method of restraint is used. The use of restraints must be part of the patient's medical treatment. Restraints are considered a short-term intervention; once they have been applied, regular assessments are needed to determine whether they should be continued.
8. **The correct answer is 3.** The poison control centre phone number should be visible on the telephone in homes with young children. In all cases of suspected poisoning, this number should be called immediately, before any intervention.
9. **The correct answer is 4.** Having a family member with the patient at all times is an unrealistic expectation; a trained sitter may be used if constant observation is required. Attending to personal needs, offering diversionary activities, and camouflaging IV lines may help to avoid the need for a restraint.

Chapter 37

1. **The correct answer is 1.** As patients with diabetes often have decreased sensation in their feet, feet should be inspected daily for signs of skin breakdown or infection; changes in colour, temperature, and sensation; and any discoloration or thickening of toenails. Daily inspection can help decrease the development of foot ulcers and subsequent complications.
2. **The correct answer is 3.** Psoriasis is a chronic inflammatory skin condition, the exact cause of which is unknown, and there is currently no cure. It is thought to be an immune-mediated disease whereby the person's immune system reacts against its own cells. It is not contagious and cannot be passed from one person to another. It is not related to poor hygiene.
3. **The correct answer is 3.** With her chronic disease, she may have decreased sensation and circulation, and an increased healing time. She is at a higher risk of developing infection and foot ulcers, which are difficult to treat and slow to heal.
4. **The correct answer is 2.** The skin holds information about the body's circulation, nutritional status, and signs of systemic disease.
5. **The correct answer is 3.** Pallor in a patient with dark skin appears ashen, grey, or dull.
6. **The correct answer is 2.** Inflammation is not easily recognized, and it is often necessary to palpate the skin for increased warmth, taut surfaces that may indicate edema, and induration (hardening of the tissue) as redness at the site of the inflammation is not able to be seen in a dark-skinned patient.
7. **The correct answer is 1.** Gag reflex should be tested in order to avoid aspiration of oral contents during oral hygiene care.
8. **The correct answer is 1.** The patient should always be included in the care plan. Cultural preferences should always be considered. If the patient is unconscious, the family can provide information on hair care preferences.
9. **The correct answer is 2.** This action prevents secretions from entering the nasolacrimal duct.
10. **The correct answer is 4.** It is important to do all these actions.

Chapter 38

1. **The correct answer is 1.** Anemia, a lower than normal hemoglobin level, is a result of decreased hemoglobin production, increased red blood cell destruction, blood loss, or a combination of these factors. Patients will have complaints of fatigue,

decreased activity tolerance, and increased breathlessness, as well as pallor (especially seen in the conjunctiva of the eye) and an increased heart rate.

2. **The correct answer is 2.** Carbon monoxide is the most common toxic inhalant that decreases the oxygen-carrying capacity of blood. The affinity for hemoglobin to bind with carbon monoxide is greater than 200 times its affinity to bind with oxygen, creating a functional anemia. Because of the bond's strength, carbon monoxide is not easily dissociated from hemoglobin, making the hemoglobin unavailable for oxygen transport.
3. **The correct answer is 1.** Hypovolemia is caused by conditions such as shock and severe dehydration resulting from extracellular fluid loss and reduced circulating blood volume. With a significant fluid loss, the body tries to adapt by increasing the heart rate and peripheral vasoconstriction to increase the volume of blood returned to the heart and, in turn, increase the cardiac output.
4. **The correct answer is 3.** Fever increases the tissues' need for oxygen, and as a result, carbon dioxide production also increases. If the febrile state persists, the metabolic rate remains high and the body begins to break down protein stores, resulting in muscle wasting and decreased muscle mass. Respiratory muscles such as the diaphragm and intercostal muscles are also wasted.
5. **The correct answer is 1.** Left-sided heart failure is an abnormal condition characterized by impaired functioning of the left ventricle as a result of elevated pressures and pulmonary congestion. If left ventricular failure is significant, the amount of blood ejected from the left ventricle drops greatly, resulting in decreased cardiac output.
6. **The correct answer is 1.** Right-sided heart failure results from impaired functioning of the right ventricle characterized by venous congestion in the systemic circulation. Right-sided heart failure more commonly results from pulmonary disease or is a consequence of long-term left-sided failure. Right-sided heart failure results from impaired functioning of the right ventricle, characterized by venous congestion in the systemic circulation. Right-sided heart failure more commonly results from pulmonary disease or from long-term left-sided failure. As the failure continues, the amount of blood ejected from the right ventricle declines, and blood begins to "back up" in the systemic circulation. Clinically, the patient has weight gain, distended neck veins, hepatomegaly and splenomegaly, and dependent peripheral edema.
7. **The correct answer is 2.** Cyanosis, blue discoloration of the skin and mucous membranes caused by the presence of desaturated hemoglobin in capillaries, is a late sign of hypoxia. The presence or absence of cyanosis is not a reliable measure of oxygenation status.
8. **The correct answer is 1.** A person who starts smoking in adolescence and continues to smoke into middle age has an increased risk for cardiopulmonary disease and lung cancer.
9. **The correct answer is 3.** Frequent changes of position are simple and cost-effective methods for reducing the risks of stasis of pulmonary secretions and decreased chest wall expansion.
10. **The correct answer is 4.** The most effective position for patients with cardiopulmonary diseases is the 45-degree semi-Fowler's position, using gravity to assist in lung expansion and reduce pressure from the abdomen on the diaphragm.
11. **The correct answer is 1.** If an unexpected outcome resulting from a chest tube is a tension pneumothorax, it is important

to determine if the cause is related to the chest tube being clamped, kinked, or occluded.

12. **The correct answer is 4.** Applying intermittent suction while withdrawing the catheter prevents injury to tracheal mucosal lining.

Chapter 39

1. **The correct answer is 1.** Hypokalemia is one of the most common electrolyte imbalances, in which an inadequate amount of potassium circulates in extracellular fluid (ECF). When severe, hypokalemia can affect cardiac conduction and function. Because the normal amount of serum potassium is so small, fluctuations are poorly tolerated. The most common cause of hypokalemia is the use of potassium-wasting diuretics such as thiazide and loop diuretics.
2. **The correct answer is 4.** An infant's proportion of total body water (70% to 80% total body weight) is greater than that of children or adults. Infants are not protected from fluid loss because they ingest and excrete a relatively greater daily water volume than do adults. Therefore, they are at a greater risk for FVD and hyperosmolar imbalance because body water loss is proportionately greater per kilogram of weight. In addition, infants are dependent on others for fluid intake.
3. **The correct answer is 2.** Older adults experience a number of age-related changes that can affect fluid, electrolyte, and acid-base balances. They have a decreased thirst sensation, which may affect their oral intake of fluids. The kidneys have a decrease in the glomerular filtration rate and in the number of filtering nephrons. These changes can mean that in the presence of sodium depletion or overload, the older adult may be unable to maintain homeostasis, and the imbalance is instead worsened.
4. **The correct answer is 4.** For patients in health care settings, measurement of intake and output is a nursing intervention routinely used for patients following a procedure, patients who are febrile, patients with restricted fluids, or patients who receive diuretic or intravenous therapy. Output includes urine, diarrhea, vomitus, gastric suction, and drainage from postsurgical wounds or other tubes.
5. **The correct answer is 1.** Health promotion activities in the area of fluid, electrolyte, and acid-base imbalances focus primarily on patient teaching. Patients and caregivers need to recognize risk factors for these imbalances and implement appropriate preventive measures.
6. **The correct answer is 1.** Under no circumstances should potassium chloride (KCl) be given by intravenous push. A direct intravenous infusion of KCl can be fatal. If an intravenous fluid is to have additives, a physician's order must be obtained that includes the required additives.
7. **The correct answer is 1.** The patient's microflora and contamination by insertion are initially controlled for in the procedure for intravenous insertion. However, the other factors are controlled through conscientious use of infection control principles. This begins with thorough hand hygiene before and after the nurse handles any component of the intravenous system.
8. **The correct answer is 3.** An infiltration occurs when intravenous fluids enter the surrounding space around the venipuncture site. This is manifested as swelling (from increased tissue fluid) and pallor and coolness (caused by decreased circulation) around the venipuncture site.
9. **The correct answer is 3.** Although many policies recommend replacing PVAD and rotating sites to prevent phlebitis, the most recent evidence-informed review suggests that this is

unnecessary, is costly and may increase patient discomfort unnecessarily; therefore, current recommendations are to rotate sites based on clinical indications, including painful site, redness, swelling, or hardness at the site.

10. **The correct answer is 4.** Although tachycardia and possibly some dyspnea with acute hemolytic and anaphylactic reactions will occur, the most common symptoms of circulatory overload related to blood administration are cough, dyspnea, and tachycardia. In other reactions, fever, chills, or both also occur.

Chapter 40

1. **The correct answer is 4.** Excessive daytime sleepiness (EDS) is the most common complaint of people with obstructive sleep apnea (OSA). People with severe OSA may report experiencing a disruption in their daily activities because of sleepiness.
2. **The correct answer is 2.** In hospitals and long-term care facilities, patients may have difficulty finding the time they need to rest and sleep. You should plan care to avoid awakening patients for nonessential tasks. You should schedule assessments, treatments, procedures, and routines for times when patients are awake. For example, you should not wake a stable patient to check vital signs.
3. **The correct answer is 4.** The use of nonprescription sleeping medications is not advisable. Patients should learn the risks of such drugs. Over the long term, these drugs can lead to further sleep disruption even when they initially seemed to be effective. Older adults should be cautioned about using over-the-counter antihistamines because of their long duration of action that can cause confusion, constipation, urinary retention, and increased risk of falls.
4. **The correct answer is 4.** Patients should be cautioned about the dosage and use of herbal compounds because active ingredients can vary from product to product. Herbal compounds may interact with prescribed medication, and concurrent use should be avoided.
5. **The correct answer is 1.** Although dreams occur during both nonrapid eye movement (NREM) and rapid eye movement (REM) sleep, the dreams of REM sleep are more vivid and elaborate and are believed to be functionally important to learning, memory processing, and adaptation to stress.
6. **The correct answer is 3.** Alcohol can initially make a person feel drowsy; however, it can also cause a person to awaken during the night and can cause difficulty returning to sleep.
7. **The correct answer is 1.** Limiting alcohol, caffeine, and nicotine and decreasing fluids two to four hours before sleep may promote sleep for older adults.
8. **The correct answer is 3.** The Canadian Paediatric Society recommends that apparently healthy infants be placed in the supine position during sleep because of an association between the prone position and the occurrence of sudden infant death syndrome (SIDS).
9. **The correct answer is 4.** Narcolepsy is a dysfunction of mechanisms that regulate the sleep and wake states. Excessive daytime sleepiness (EDS) is the most common complaint associated with this disorder. Brief daytime naps no longer than 20 minutes help reduce subjective feelings of sleepiness. During the day, the person may suddenly feel an overwhelming wave of sleepiness and fall asleep; REM sleep can occur within 15 minutes of falling asleep.
10. **The correct answer is 4.** Sleep needed during the school years is individualized because of varying activity and health levels.

Six-year-olds average 11 to 12 hours of sleep nightly, whereas 11-year-olds sleep 9 to 10 hours. Six- or seven-year-olds can usually be persuaded to go to bed by encouraging quiet activities.

Chapter 41

1. **The correct answer is 3.** Imagery is a visualization technique used by the patient to decrease pain sensation by focusing on pleasurable images. Distraction (2) involves directing the patient's attention to something within the immediate environment to reduce pain awareness. Relaxation exercises (4) involve techniques that lessen physical and mental tension through focus on consciously releasing muscle tension. Recall (1) is not a nonpharmacological pain strategy.
2. **The correct answer is 4.** Referred pain is perceived in an area distant from its point of origin. Transient pain (1) is brief and passes quickly and may be at its point of origin. Superficial pain (2) originates in the skin or subcutaneous tissue. Phantom pain (3) may reflect injury to the peripheral nervous system and may occur in a person who has lost part of a limb.
3. **The correct answer is 3.** The Northern Pain Scale is a self-report scale for developmentally age-appropriate young Inuit children experiencing acute pain episodes. The FLACC tool (1) is most appropriate for children who are nonverbal. The Numerical Rating Scale is indicated for children (>9 years) and adults experiencing acute pain who are able to use numbers to rate the intensity of their pain. The Wong-Baker Scale (4), although a self-report scale specific for this age group, is not as culturally appropriate.
4. **The correct answer is 3.** Increased blood pressure is an involuntary sympathetic nervous system response to moderate pain. Heart rate (2) would increase due to the activation of the sympathetic nervous system. Restlessness (1) and protection of the painful area (4) are behavioural responses.
5. **The correct answer is 4.** You can only make an accurate diagnosis of pain after you have performed a complete patient assessment. You will consider the patient's withdrawal from communication, grimacing, moaning, and verbalizations of discomfort.
6. **The correct answer is 3.** Descriptive scales are used both to assess pain severity and to evaluate changes in a patient's condition. A rating of 7 or more on a 0 to 10 scale requires immediate attention. The dose was insufficient.
7. **The correct answer is 3.** Teaching patients about pain reduces anxiety and helps them to achieve a sense of control. When a patient is anticipating pain, you need to explain procedures and any associated discomfort. A confident explanation of the procedure helps you to gain a patient's trust. When patients are informed about an upcoming painful experience, they often perceive the actual experience as less unpleasant.
8. **The correct answer is 4.** Relaxation and guided imagery are examples of mind-body interactions to decrease pain sensation, whereas physical interventions (2) are techniques that focus solely on the body. Adjuvants are drugs used to enhance the effect of opioids (1), whereas patient-controlled analgesia (3) is a drug delivery system.
9. **The correct answer is 3.** One way to maximize pain relief while minimizing drug toxicity is to administer medication on a regular around-the-clock (ATC) basis rather than on an as-needed (prn) basis. The Canadian Pain Society has stated that if pain is anticipated for the majority of the day, ATC administration should be considered to prevent breakthrough pain, which is hard to control once it appears.

10. **The correct answer is 2.** A drug delivery where the patient, not the nurse (1) or family (3), is in control of the delivery of pain management program. Although the patient may use less medication because it is self-administered before the pain becomes too severe, the primary goal of this delivery system is not to minimize the quantity of analgesia needed to control pain (4).

Chapter 42

1. **The correct answer is 3.** Carbohydrates are the main source of energy in the diet.
2. **The correct answer is 2.** Essential nutrients are generally supplied by food.
3. **The correct answer is 4.** When the intake of nitrogen exceeds the output, the body is in positive nitrogen balance, which is required for growth, normal pregnancy, maintenance of lean muscle mass and vital organs, and wound healing.
4. **The correct answer is 2.** Income as the major determinant is positively correlated with food selection and quantity.
5. **The correct answer is 1.** When a patient is unable to take fluid or food by eating normally over an extended period of time, nutrients are needed, and giving liquid nutrients through a nasoenteral feeding tube will ensure adequate nutrition.
6. **The correct answer is 4.** The nutrient content claim *light* is permitted only on foods reduced in fat or reduced in calories. The percent of reduction in calories or fat has not been established for the claim *light*.
7. **The correct answer is 4.** Whole milk helps ensure adequate intake of fatty acids necessary for brain and neurological development.
8. **The correct answer is 3.** The stronger side can do the work of chewing and swallowing.
9. **The correct answer is 3.** Age-related factors affect appetite, comfort, and digestion of food.
10. **The correct answer is 2.** Filling the tube with water and clamping it after each feeding will *most* likely prevent clogging of a nasogastric feeding tube.

Chapter 43

1. **The correct answer is 2.** The normal adult urine output is 1500 to 1600 mL/day.
2. **The correct answer is 1.** Renal alterations result from factors that cause injury directly to the glomeruli or renal tubule, interfering with their normal filtering, reabsorptive, and secretory functions. Selected causes are transfusion reactions, diseases of the glomeruli, and systemic diseases such as diabetes mellitus.
3. **The correct answer is 2.** Postrenal alterations result from obstruction to the flow of urine in the urinary collecting system anywhere between the renal pelvis and the urethral meatus. Urine is formed by the urinary system but cannot be eliminated by normal means. Urinary obstruction can be caused by calculi (stones), blood clots, or tumours.
4. **The correct answer is 3.** The urine is normally acidic, which inhibits bacterial growth and may prevent UTIs. Residual urine left in the bladder becomes alkaline and is an ideal medium for microbial growth.
5. **The correct answer is 3.** Hospital-acquired UTIs are often related to poor hand hygiene and urinary catheterization. The introduction of a catheter through the urethra provides a direct route for microorganisms to enter the bladder.
6. **The correct answer is 1.** The urine appears concentrated and cloudy because of the presence of white blood cells (WBCs) or bacteria.

7. **The correct answer is 1.** Prompted voiding is a useful strategy for patients with cognitive and/or physical impairment who rely on caregiver assistance.
8. **The correct answer is 3.** With stress incontinence, urine loss results from increased intra-abdominal pressure (e.g., coughing, sneezing, laughing, lifting). It usually involves a small volume of urine loss (less than 50 mL) and usually occurs in women or in men following radical prostatectomy. Pregnancy and delivery, weak pelvic floor muscles, heavy lifting, and obesity are sometimes contributing factors.
9. **The correct answer is 1.** The drainage bag should never be raised above the level of the patient's bladder. It should hang on the bed frame or wheelchair without touching the floor. Urine in the bag and tubing can become a medium for bacteria, and infection is likely to develop if urine flows back into the bladder.
10. **The correct answer is 4.** Care must be taken to ensure that whatever type or size of condom is used, blood supply to the penis is not impaired. Therefore, the condom catheter should be snug and secure but should not cause constriction of blood flow.
11. **The correct answer is 3.** In many cases, incontinence can be improved through careful assessment, determination of possible causes and contributors, and implementation of management strategies. Referral to a local continence service that can provide this expertise and reliable web-based resources can be a source of information for the patient.
12. **The correct answer is 2.** Research has demonstrated that weight loss in the overweight individual can be an effective strategy in improving incontinence, particularly in women with stress incontinence.

Chapter 44

1. **The correct answer is 4.** Most nutrients and electrolytes are absorbed in the small intestine, specifically in the duodenum and jejunum.
2. **The correct answer is 3.** Lactose intolerance is the inability to digest lactose, which is the predominant sugar in milk and milk products. Lactose intolerance is caused by a shortage of the enzyme lactase. Lactase is normally produced by the cells that line the small intestine and is needed to digest lactose; however, lactase is genetically programmed to disappear in adulthood in everyone except in individuals of northern European ancestry. As a result, many adults cannot digest lactose, which results in diarrhea, gaseous distension, and cramping.
3. **The correct answer is 4.** Fecal occult blood testing (FOBT), or the guaiac test, is a common laboratory test that can be done at home or at the patient's bedside. This test measures microscopic amounts of blood in the feces. FOBT is useful as a diagnostic screening test for colon cancer.
4. **The correct answer is 1.** Antidiarrheal opiate agents decrease intestinal muscle tone to slow the passage of feces. Opiates inhibit the peristaltic waves that move feces forward but they also increase segmental contractions that mix the intestinal contents and expose them to the mucosal-absorbing surface.
5. **The correct answer is 3.** An obvious sign of impaction is the inability to pass a stool for several days, despite the repeated urge to defecate. When a continuous oozing of diarrhea stool develops, impaction should be suspected. The diarrhea is the result of the liquid portion of feces, located higher in the colon, seeping around the impacted mass.
6. **The correct answer is 4.** Cleansing enemas promote the complete evacuation of feces from the colon. The amount of solution to be instilled in an adult is 750 to 1000 mL.

7. **The correct answer is 3.** The specific signs and symptoms of intolerance to an enema include abdominal pain that is greater than a pressure sensation, abdominal cramping, abdominal distension, or rectal bleeding. The enema must be stopped. Notify the physician and obtain vital signs.
8. **The correct answer is 2.** One of the greatest problems in caring for a patient with a nasogastric tube is maintaining comfort. The tube is a constant irritation to nasal mucosa. The nurse must assess the condition of both nares and mucosa for inflammation and excoriation.
9. **The correct answer is 1.** The stool discharged from an ostomy is called *effluent*.
10. **The correct answer is 1.** A nurse trained to care for ostomy patients is an enterostomal therapist (ET).

Chapter 45

1. **The correct answer is 2.** Footdrop is the inability to dorsiflex and invert the foot because of peroneal nerve damage. The foot is permanently fixed in plantar flexion and the person is therefore unable to lift the toes off the ground.
2. **The correct answer is 3.** The effects of bed rest or immobilization on the muscular system include reduced muscle mass, muscle weakness, and muscle atrophy.
3. **The correct answer is 1.** After bed rest, patients usually have increased pulse rate and decreased pulse pressure and blood pressure. A large decrease in blood pressure when arising to a sitting or standing position (a drop of 20 mm Hg or more in systolic blood pressure and of 10 mm Hg in diastolic blood pressure) is known as orthostatic hypotension and can result in light-headedness and fainting.
4. **The correct answer is 3.** Elastic stockings (sometimes called thromboembolic device hose, or TED) help to maintain external pressure on the muscles of the lower extremities and thus may promote venous return.
5. **The correct answer is 3.** Immobility can have a significant effect on the older adult's levels of health, independence, and functional status.
6. **The correct answer is 4.** Increased activity may result in symptoms associated with activity intolerance (e.g., increased pulse, changes in blood pressure, increased respirations, and decreased level of comfort). This can jeopardize the patient's safety.
7. **The correct answer is 1.** The trapeze bar is a triangular device that descends from a securely fastened overhead bar attached to the bed frame. It allows the patient to use the upper extremities to raise the trunk off the bed, to assist in transfer from the bed to a wheelchair, or to perform upper arm exercises.
8. **The correct answer is 2.** The patient in the prone position is lying face or chest down.
9. **The correct answer is 3.** When a patient is in supported Fowler's position, placement of a small pillow or roll under the thigh prevents occlusion of the popliteal artery from pressure from body weight. It also prevents hyperextension of the knee.
10. **The correct answer is 4.** The body requires additional energy to heal pressure ulcers. Dietitians are trained in thorough assessment of caloric requirements and intake for effective wound healing and, thus, are essential members of the health care team looking after patients with skin breakdown. In addition, dietitians are knowledgeable about different sources of nutrition, including supplements or tube feeding, if required.

Chapter 46

1. **The correct answer is 4.** When the skin is being compressed, blood flow is slowed and the skin becomes pale. After the pressure is relieved, the skin in the affected area turns red (erythema), which is a result of the blood vessels expanding (vasodilation) to allow more blood into the area to overcome the ischemic episode. This process is called *normal reactive hyperemia*. Assess the reddened area by pressing a fingertip over it. If the area blanches (turns white or a pale colour) and the erythema returns when the finger is removed, the reactive hyperemia is likely transient. If, however, the reddened area

does not blanch when finger pressure is applied (abnormal reactive hyperemia), suspect deep tissue damage.

2. **The correct answer is 1.** A stage I pressure ulcer is an observable pressure-related alteration of intact skin, whose indicators, as compared with an adjacent or opposite area on the body, may include changes in skin temperature (warmth or coolness), tissue consistency (firm or beefy feel), and sensation (pain or itching).
3. **The correct answer is 4.** If purulent or suspicious-looking wound drainage is present or there is a change in a previously healing chronic wound, obtaining a specimen of the drainage for culture may be necessary. The wound culture sample should never be collected from old drainage. Resident colonies of bacteria from the skin grow within exudate and may not be the true causative organisms of a wound infection. Before culturing a wound, clean the base of the wound with normal saline to remove superficial slough and debris. Select the cleanest part of the wound bed (granulating tissue is optimal), press the swab into a 1-cm square area of this cleanest part of the wound, and rotate fully, pressing to express fluid beneath the surface of the wound bed.
4. **The correct answer is 3.** When evisceration occurs, place sterile towels soaked in sterile saline over the extruding tissues to reduce chances of bacterial invasion and drying of the tissues. If the organs protrude through the wound, blood supply to the tissues is compromised. The patient should be allowed nothing by mouth (NPO), observed for signs and symptoms of shock, and prepared for emergency surgery.
5. **The correct answer is 3.** Serous drainage is clear, watery plasma.
6. **The correct answer is 3.** Ensuring the patient understands the plan of care will decrease anxiety and increase the patient's feeling of control. Pain can also have a negative impact on wound healing; thus, assessing the need for analgesia and providing it before the dressing change supports optimal healing and patient comfort and control.
7. **The correct answer is 3.** Exposure to fecal and urinary incontinence creates a caustic environment on the skin that leads to excoriation and further breakdown, once the skin is no longer intact. An incontinence cleanser and a moisture barrier ointment will remove urine and feces from the skin, leaving a protective (usually silicone-based) barrier that repels moisture.
8. **The correct answer is 4.** Hydrocolloid dressings are dressings with complex formulations of colloidal, elastomeric, and adhesive components that are both adhesive and occlusive. The wound contact layer of this dressing forms a gel as fluid is absorbed and maintains a moist healing environment.
9. **The correct answer is 3.** An abdominal binder will support the wound and reduce stress on large abdominal incisions that are vulnerable to tension or stress as the patient moves or coughs.
10. **The correct answer is 4.** The body requires additional energy to heal pressure ulcers. Dietitians are trained in thorough assessment of caloric requirements and intake for effective wound healing and, thus, are essential members of the health care team looking after patients with skin breakdown. In addition, dietitians are knowledgeable about different sources of nutrition, including supplements or tube feeding, if required.

Chapter 47

1. **The correct answer is 2.** A kinesthetic sense enables a person to be aware of the position and movement of body parts without seeing them.

2. **The correct answer is 1.** Stereognosis is a sense that allows a person to recognize an object's size, shape, and texture.
3. **The correct answer is 3.** When a person receives multiple sensory stimuli and cannot perceptually disregard or selectively ignore some stimuli, sensory overload occurs. The patient in constant pain or who undergoes frequent monitoring of vital signs is at risk. Multiple stimuli can combine to cause overload.
4. **The correct answer is 2.** Proprioceptive changes after the age of 60 years include increased difficulty with balance, spatial orientation, and coordination.
5. **The correct answer is 4.** For a patient with hearing impairment, you should face the patient when speaking, use simple sentences, and speak more slowly and at a normal volume.
6. **The correct answer is 4.** The nursing health history includes assessment of the nature and characteristics of sensory alterations or any problem related to an alteration. The nurse begins by asking the patient to describe the sensory deficit. For example, "How does your hearing now compare with your hearing a year ago?"
7. **The correct answer is 2.** Advise older adults as follows: Do not drive during rush hour. Use rear-view and side-view mirrors when changing lanes. Avoid driving at dusk or at night. Drive slowly, but not too slowly. Keep your car in good working condition.
8. **The correct answer is 3.** Hearing loss caused by noisy environments was once thought to affect primarily older individuals; however, recent research has observed this loss in youth. As a nurse, you should routinely teach parents and children to take precautions when involved in activities associated with high-intensity noise. You should assess patients for noise exposure and participate in providing hearing conservation classes for teachers, students, and patients.
9. **The correct answer is 3.** Olfaction is the sense of smell. A patient who cannot smell smoke may not know that something is burning. A smoke detector would be essential.
10. **The correct answer is 1.** When senses are impaired, the sense of self is impaired. Initially, a person may withdraw by avoiding communication or socialization with others in an attempt to cope with the sensory loss.
2. **The correct answer is 3.** If a patient regularly uses prescription or over-the-counter medications, the surgeon or anesthesiologist may temporarily discontinue the drugs before surgery or adjust the dosages. Certain medications have special implications for the surgical patient, creating greater risks for complications or interacting negatively with anesthetic agents.
3. **The correct answer is 2.** The patient who smokes is at greater risk for postoperative pulmonary complications than a patient who does not.
4. **The correct answer is 2.** The family is an important resource for a patient with physical limitations and provides the emotional support needed to motivate the patient to return to a previous state of health. Often, a family member can become the patient's coach, offering valuable support during the postoperative period.
5. **The correct answer is 1.** Accurate recording of intake and output helps assess renal and circulatory function. For example, you measure all sources of output, including urine, surgically placed drains, gastric drainage, and drainage from wounds, and note any insensible loss from diaphoresis.
6. **The correct answer is 3.** Position the patient on one side with the face downward and the neck slightly extended to facilitate a forward movement of the tongue and the flow of mucous secretions out of the mouth.
7. **The correct answer is 4.** To promote normal venous return and circulatory blood flow, encourage patients to perform leg exercises at least every hour while awake. Other measures include applying elastic stockings or sequential compression device as ordered, encouraging early ambulation, positioning the patient so that blood flow is not interrupted, administering anticoagulant drugs as ordered, and promoting adequate fluid intake.
8. **The correct answer is 2.** International normalized ratio (INR) and activated partial thromboplastin time (APTT) indicate the clotting ability of blood, which if greater than normal reveal patients at risk for bleeding tendencies.
9. **The correct answer is 2.** Maintaining an upright position facilitates diaphragm excursion and enhances expansion of the thorax.
10. **The correct answer is 4.** Malignant hyperthermia is a potentially lethal condition that can occur in patients who received general anaesthesia. It should be suspected when there is unexpected tachycardia and tachypnea; jaw muscle rigidity; body rigidity of limbs, abdomen, and chest; or hyperkalemia. Temperature elevation is a late sign.

Chapter 48

1. **The correct answer is 2.** The obese patient is susceptible to poor wound healing and to wound infection because of the structure of fatty tissue, which contains a poor blood supply. This slows delivery of essential nutrients and enzymes needed for wound healing.
